That amphetamines are anorectic is well known; however, the extent of the effect may be overstated. Bray and Greenway (1999) summarized the studies of obesity treatments, wherein they cited a large review of more than 200 short-term (3 months) double-blind studies of various noradrenergic agents, including amphetamine and amphetamine derivatives. Patients taking stimulants were twice as likely as those taking placebo to lose 1 lb/week; however, the percentage of patients who lost 3 lb/week was quite small (10%). The mean difference between drug and placebo weight losses was 0.5 lb/week. Bray and Greenway (1999) also noted that long-term (>14 weeks) double-blind studies with amphetamine proper have not been done, but the noradrenergic drugs diethylpropion and phentermine were associated with significantly more weight loss than was placebo. However, few studies were done (five total), and they had small sample sizes (10–36 people in each study), making the results difficult to interpret. A small study found that high doses of amphetamine (30 mg) decreased overall caloric intake but did so primarily through a decrease in fat consumption; carbohydrate consumption actually increased (Foltin et al. 1995). This mild effect on appetite is important when considering the use of stimulants in elderly patients who lack both energy and motivation and have poor appetite.

Depression

No controlled trials have investigated the use of stimulants in depression to date. Most of the evidence for stimulant utility in depression derives from case series. The bulk of the current evidence derives from case series by Feighner et al. (1985) and Fawcett et al. (1991), which suggested the efficacy of stimulants combined with MAOIs and MAOI/TCA combinations, as well as their safety in not causing hypertensive or hyperthermic crises, and case series by Stoll et al. (1996) and Metz and Shader (1991), in which a combination of stimulant and selective serotonin reuptake inhibitor (SSRI) was used. Another case series argued for amphetamine's ability to augment an antidepressant effect in patients with only partial response, although the effects were, not unexpectedly, primarily in improving fatigue and apathy (Masand et al. 1998).

In an open-label trial of depressed cancer patients, both amphetamine and methylphenidate were reported to improve depressive symptoms to the same extent, and effects were seen within 2 days. In

this series, stimulants did not cause anorexia; in fact, they improved appetite in more than half of the patients studied (Olin and Masand 1996), suggesting that these agents are not contraindicated solely on the basis of concerns about anorexia.

In a recent review, Orr and Taylor (2007) noted the paucity of high-quality data and suggested a possible role for stimulants in depression, particularly as adjunctive agents, in specific patient subgroups.

The utility of modafinil in depressive states is still not well characterized, the majority of evidence being either anecdotal or retrospective. More work is likely forthcoming, but there are two studies that bear some examination. The mood-altering properties of modafinil were studied in 32 normal volunteers, in a double-blind, crossover, inpatient study (Taneja et al. 2007). Modafinil had positive results on general mood, especially on alertness and energy measures, but also had a negative effect on feeling calm (i.e., increased anxiety). Whether similar divergent effects would be found in depression remains to be seen.

A double-blind, placebo-controlled trial (Dunlop et al. 2007) examining the effects of modafinil initiated at the outset of treatment with an SSRI in depressed patients with fatigue found no difference in the primary outcome measure of the Epworth Sleepiness Scale, but some improvement in the hypersomnia items of the 31-item Hamilton Rating Scale for Depression. However, power to detect differences was limited by premature termination of the study. Two subjects (both on SSRIs) developed suicidal ideation in their respective second weeks of treatment with modafinil; one required hospitalization. While it is not clear what role modafinil played—post hoc analysis of the suicide item in the rating scales showed no difference from the placebo group—continued vigilance in this area is recommended. Two other controlled trials (DeBattista et al. 2003; Fava et al. 2005) and two open-label trials (DeBattista et al. 2001; Menza et al. 2000) suggest that modafinil may have some utility as an augmentation agent to antidepressants in depressed patients with fatigue or excessive sleepiness. Further study is needed.

CONCLUSION

The safety and efficacy of stimulants for the treatment of ADHD have been established. Modafinil and armodafinil are also firmly established as efficacious as wakefulness-promoting agents in narcolepsy, sleep apnea, and shift work sleep disorder. The utility of these drugs in other areas is being examined. Although there is intense interest in the potential use of stimulants and modafinil in other psychiatric and neurobehavioral conditions, controlled studies on their safety and efficacy are limited. It is unclear why stimulants have not been extensively investigated for clinical utility over the years, except for the treatment of ADHD. The approval of armodafinil, as the newest of the wakefulness-promoting compounds, may perhaps spur further research. Well-designed large-scale controlled trials are needed to define and characterize the role of stimulants and modafinil in various psychiatric illnesses. It is hoped that this will be an area of continued interest and development, from the elucidation of the molecular mechanisms of stimulants and modafinil to the demonstration through controlled trials of their potential clinical safety and benefits.

Chapter 44. Electroconvulsive Therapy

ELECTROCONVULSIVE THERAPY: INTRODUCTION

Over the past 70 years, electroconvulsive therapy (ECT) has been proven to be one of the most effective somatic treatments for mood disorders (Abrams 1992). Although the serendipitous discovery of psychotropic medications such as chlorpromazine and iproniazid in the 1950s revolutionized psychiatric treatment, clinicians and researchers soon recognized the limitations of psychotropic medications and ECT remained an important therapeutic alternative. The continued use of ECT has provided support for ECT-related research, including exploration of clinical indications, techniques to maximize efficacy and minimize toxicity (especially cognitive and cardiac side effects), and therapeutic mechanisms of action. In this chapter, we review the history of ECT, the preclinical and clinical data on the mechanism of action of ECT, and the relevant literature related to efficacy. We also provide practical guidelines for the administration of ECT, including the efficacy of ECT in treating various psychiatric disorders as well as appropriate patient selection, stimulus settings and electrode placement, pretreatment medical evaluation, and management of the patient during acute, continuation, and maintenance courses of ECT. Finally, we outline an overview of some recent developments to treat depression with nonconvulsive stimuli such as transcranial magnetic stimulation (TMS).

HISTORY OF ECT

The development of ECT occurred at a time when few s22(c)matic treatments were available f22(c)r

Most serious efforts to understand the mechanisms of ECT have focused on changes in neurotransmitter systems and intracellular biochemical processes (for reviews, see Fochtmann 1994; Newman et al. 1998; Nutt and Glue 1993). Researchers have identified changes possibly leading to therapeutic benefits at cellular and neural system levels using neurochemical information about ECT from studies of electroconvulsive shock (ECS) in rodents. Repeated seizures, whether electrically induced or spontaneous, clearly result in short- and long-term changes in brain function. The assumption is that the effects of repeated generalized seizures in animals reflect the effects of ECT in patients with psychiatric disorders (Lerer et al. 1984).

An alternative strategy is to examine the effects of ECT on central nervous system (CNS) processes for which there is better mechanistic understanding. The assumption is that the effects of ECT on CNS processes are related to the known antidepressive effects of other treatments including psychotherapy, pharmacotherapy, and newer brain stimulation techniques such as deep brain stimulation and TMS. Advances in understanding the neurocircuitry and cellular changes associated with major psychiatric disorders offer hope in defining the effects of ECT and are likely to be important. Although all of these strategies have weaknesses, the anticonvulsant hypothesis described below explains both the effects of ECT on an intracellular level and the efficacy of ECT in relation to the anticonvulsant medications used to treat mood disorders.

Anticonvulsant Hypothesis

One of the most popular theories defining the mechanism of action of ECT is that the antidepressive efficacy is directly correlated with the anticonvulsant effect of ECT. That is, the therapeutic effect of ECT is proportional to an increase in the seizure threshold during ECT; successive ECT treatments cause both an increase in seizure threshold and a decrease in seizure duration (Sackeim 1999). This theory focuses on changes in neurotransmitter systems and intracellular biochemical processes and is supported by preclinical data of the effect of ECT in modulating the seizure threshold.

γ-Aminobutyric acid (GABA) is the predominant inhibitory transmitter in the brain and is a target for multiple anticonvulsant drugs (e.g., barbiturates, benzodiazepines). Data from animal studies demonstrate increases in the threshold for bicuculline- and pentylenetetrazole-induced seizures following a series of ECS treatments (Nutt et al. 1981; Plaznik et al. 1989). Because bicuculline and pentylenetetrazole act by inhibiting GABA type A ($GABA_A$) receptors, these findings suggest that ECT results in changes in GABAergic inhibition. In addition, GABA levels increase in certain CNS regions after ECS (Green et al. 1982), and there is evidence from magnetic resonance spectroscopy that ECT increases GABA levels in the occipital cortex in humans (Sanacora et al. 2003). These changes in GABA levels suggest that an increase in tonic inhibition may occur after repeated seizures, and effects on GABA-mediated tonic inhibition are increasingly recognized as an important aspect of several neuroactive drugs (Farrant and Nusser 2005). Changes in the $GABA_A$ receptor–chloride channels that are the primary postsynaptic GABA receptors are less certain (Fochtmann 1994), although it is clear that different receptor subtypes contribute to tonic and phasic (synaptic) inhibition. There is also evidence that ECS enhances the function of $GABA_B$ receptors that mediate presynaptic and postsynaptic inhibition (Lloyd et al. 1985), and this is likely to contribute to an overall depression of CNS excitation.

An interesting finding in rodents is that repeated seizures cause the release of an anticonvulsant substance into cerebrospinal fluid. Anticonvulsant activity can be transferred to treatment-naive animals by intracerebroventricular injections of cerebrospinal fluid from animals that have experienced seizures (Tortella and Long 1985, 1988). Tortella et al. (1989) summarized evidence that the anticonvulsant substance is likely to be an endogenous opioid and that treatment with naloxone, an opiate receptor antagonist, blocked the anticonvulsant effects of ECS. There is also evidence that upregulation of delta (δ) opioid receptor binding sites (e.g., sites for D-alanine-D-leucine enkephalin) occurs after repeated seizures (Hitzemann et al. 1987). Whether similar changes occur in humans is

speculative, and, to date, efforts to lengthen ECT-induced seizures using naloxone have not been successful (Prudic et al. 1999; Rasmussen and Pandurangi 1999).

Efforts to identify anticonvulsant mechanisms in ECT must account for changes in both seizure threshold and duration because different mechanisms may govern the two processes. Of note is the finding that adenosine is released extracellularly during seizures and may play a role in seizure termination. Adenosine is an important inhibitory neuromodulator that acts on several receptor types. Adenosine A_1 receptors are upregulated in the cortex after ECS, but not in the hippocampus or striatum (Gleiter et al. 1989). Clinically, adenosine receptor antagonists such as caffeine and theophylline prolong ECT-induced seizures (Hinkle et al. 1987), with less effect on seizure threshold (McCall et al. 1993a). Furthermore, theophylline use has been associated with prolonged seizures and status epilepticus during ECT (Rasmussen and Zorumski 1993). These observations suggest that release of adenosine, and perhaps increased sensitivity of certain adenosine receptors, may contribute to decreases in seizure duration during ECT, although caffeine and theophylline have other effects that could influence excitability including phosphodiesterase inhibition and release of calcium from intracellular stores (Sawynok and Yaksh 1993).

Much of the focus in studying anticonvulsant mechanisms of ECT has centered on changes in neural inhibition after repeated seizures. It is also important to consider how ECT influences excitation, particularly the glutamate system, which serves as the predominant mode of fast excitatory transmission in the CNS. Seizures are accompanied by acute release of glutamate, but we have little information about the effects of repeated seizures on glutamate release, uptake, and receptors. Although the brain damage that accompanies status epilepticus appears to result, in part, from excessive activation of *N*-methyl-D-aspartate (NMDA)–type glutamate receptors (Clifford et al. 1989), seizure-related brain damage typically requires more than 20 minutes of continuous activity and is therefore unlikely to be relevant to ECT (Devanand et al. 1994; Gruenthal et al. 1986). Furthermore, there is evidence that repeated use of ECS actually prevents seizure-related brain damage in some animal models of status epilepticus (Kondratyev et al. 2001). Repeated ECS treatments increase levels of messenger RNA (mRNA) for the NR2A and NR2B subunits of the NMDA receptor and decrease levels of mRNA for the metabotropic receptor mGluR5b in dentate gyrus and the CA1 hippocampal region (Watkins et al. 1998). These effects are transient and the mRNA levels return to control values within 48 hours. Other studies suggest that repeated ECS treatments decrease NMDA receptor function by altering the potency of glycine for its regulatory site on NMDA receptors, an effect that could diminish the ability of glycine to promote opening of the NMDA ion channel by glutamate (Paul et al. 1994; Petrie et al. 2000).

Effects of Antidepressant Medications and ECT on Mood Disorders: Possible Shared Mechanisms

The efficacy of anticonvulsants as mood stabilizers supports the anticonvulsant hypothesis; this hypothesis is appealing in that it can explain the therapeutic effects of ECT in treating both mania and depression (Sackeim 1994, 1999). Yet most antidepressants are not anticonvulsants, and researchers have investigated other possible mechanisms of action that ECT and antidepressant medications may have in common to elucidate the therapeutic effects of ECT.

There are a number of common threads in the neurotransmitter changes induced by ECT and antidepressant medications. ECT, like antidepressant pharmacotherapy, has been reported to normalize hypothalamic-pituitary-adrenal axis perturbations associated with major depression (Yuuki et al. 2005). However, a more productive area of research has focused on determining how a course of ECT affects biogenic amines. Of interest is the finding that certain antidepressants cause β_1-adrenergic receptor subsensitivity, and similar effects have been observed with ECS (Nutt and Glue 1993). ECS has multiple other effects on the adrenergic system, including increased norepinephrine turnover, increased α_1-adrenergic receptor sensitivity, and possibly decreased presynaptic α

$_2$-adrenergic receptor sensitivity. ECS also enhances the function of the serotonin system, producing increased behavioral responses to serotonin agonists and possibly increases in 5-hydroxytryptamine type 2 (5-HT_2) receptor binding in the cerebral cortex (Fochtmann 1994; Nutt and Glue 1993; Sackeim 1994). The latter effect was initially observed in rodents and differs from changes induced by chronic use of antidepressant drugs. Studies in nonhuman primates question the rodent results and provide evidence that ECS diminishes 5-HT_2 binding in the cortex (Strome et al. 2005). Thus, 5-HT_2 downregulation, like β-adrenergic receptor subsensitivity, may be a mechanism common to several antidepressive treatments.

An emerging trend in research on antidepressive mechanisms is the effect of antidepressive treatments on glutamatergic and GABAergic neurotransmission. In particular, a decrease in the function of NMDA receptors appears to be a mechanism shared by several antidepressive treatments, including ECS (Petrie et al. 2000). In the case of ECS, effects on NMDA receptors appear to be mediated by changes in the glycine regulatory site on the ligand-gated ion channels. There is also evidence that ketamine, a noncompetitive NMDA receptor antagonist, has acute antidepressive properties (Berman et al. 2000; Zarate et al. 2006). Coupled with the possibility that untimely NMDA receptor activation may contribute to ECT-induced anterograde memory problems, the antidepressive effects of ketamine raise the possibility that ketamine or other NMDA receptor–blocking anesthetics may be preferred agents for use during ECT.

One of the more intriguing avenues of research for understanding the effects of ECT is the neurocircuitry of mood regulation and depression. This circuitry involves connections between and within regions of the prefrontal cortex, anterior cingulate gyrus, subgenual prefrontal cortex, anterior thalamus, and more traditional limbic structures (the hippocampus and amygdala) (Drevets 2000; Seminowicz et al. 2004). There is now evidence of structural changes including cell loss (loss of glia and possibly neurons) in several of these regions in patients with unipolar as well as bipolar mood disorders (Harrison 2002). It also appears that different antidepressive treatments may differentially affect metabolism in the neurocircuitry. Effective treatment with paroxetine appears to increase metabolism in frontal regions while decreasing metabolism in the hippocampus, whereas cognitive-behavioral therapy has the opposite effects (Goldapple et al. 2004; Seminowicz et al. 2004). ECT, in contrast, diminishes metabolism in both the prefrontal cortex and the hippocampus (Nobler et al. 2001). Although it is too early to draw firm conclusions about these observations, it is intriguing that chronic deep brain stimulation targeted toward the subgenual prefrontal region appears to be effective in a small sample of patients with treatment-resistant chronic depression (Mayberg et al. 2005), further implicating neurocircuitry changes in the biology of depression.

In addition to the imaging results noted above, there is evidence that several antidepressive treatments, including ECS, have neurotrophic effects and result in neurogenesis in the dentate gyrus of adult rodents (Madsen et al. 2000; Malberg 2000; B. W. Scott et al. 2000). These effects may result from changes in brain-derived neurotrophic factor (BDNF) and the receptor tyrosine kinase (TRK_B) through which BDNF exerts its actions, as well as from the treatment's effects on the adenylate cyclase intracellular signaling system, including cyclic adenosine monophosphate (cAMP) response element–binding protein (CREB), a downstream effector (Duman and Vaidya 1998; Nestler et al. 2002; Schloss and Henn 2004). Other evidence suggests that new neurons produced in the dentate gyrus of adult rodents have the properties of functional neurons and participate in synaptic transmission (Song et al. 2002), suggesting that antidepressive treatments, including ECT, may ultimately enhance hippocampal function. Hippocampal changes also appear to include increases in angiogenesis and possibly blood flow in specific subregions of the hippocampus (Hellsten et al. 2005; Newton et al. 2006).

Whether effects on neurogenesis are important to the therapeutic effects of ECT and other antidepressive treatments remains speculative, although elegant studies in rodents provide evidence

that neurogenesis is important to at least some behavioral effects of medications (Santarelli et al. 2003). It is uncertain whether similar neurotrophic effects occur with ECT in humans. However, studies using magnetic resonance spectroscopy to monitor regional changes in the glutamate-to-glutamine ratio (called *Glx*), a marker of local intracellular excitatory transmitter metabolism (Hasler et al. 2007), indicate that depressed subjects have low Glx values that increase to normal values with effective ECT (Michael et al. 2003; Pfleiderer et al. 2003). Changes in Glx in depressed patients treated with ECT may reflect alterations in glial function in the circuitry underlying depression.

Recent efforts to identify mechanisms contributing to the effects of ECT and antidepressant drugs have included the use of microarrays to study gene expression in multiple brain regions. Although these studies are in their infancy, some evidence indicates that rapidly acting treatments like ECT cause changes primarily in the catecholaminergic system, whereas treatments that act more slowly, like fluoxetine, act predominantly on the serotonergic system. These studies also show strong effects of ECT on BDNF and transcripts encoding proteins involved in hippocampal synaptic plasticity (Conti et al. 2007). Follow-up studies examining the effects of ECT on protein expression and downstream functioning will be important in determining their relevance to ECT's clinical actions.

EFFICACY OF ECT

Depression

Indications

The summary statement by the American Psychiatric Association Task Force on Electroconvulsive Therapy (2001) and research over the past 30 years (Abrams 1992; Fink 1979; O'Connor et al. 2001; Petrides et al. 2001) have confirmed that ECT is an effective treatment for depression in more than 80% of patients with treatment-resistant unipolar major depression or bipolar disorder. A meta-analysis of randomized, controlled trials (RCTs) performed by the UK ECT Review Group (2003) confirmed the following about the efficacy of ECT for major depression:

- ECT is more efficacious than sham ECT (shown in six RCTs; effect size, 0.91).
- ECT is more efficacious than antidepressant pharmacotherapy (18 RCTs; effect size, 0.80).
- Aspects of ECT associated with a positive response include higher total dose and bilateral electrode placement (although many studies likely underdosed patients with unilateral ECT).

It is noteworthy, however, that several of these studies compared the response rates in patients receiving ECT with the response rates in patients receiving subtherapeutic doses of antidepressants.

Given these data, ECT should no longer be considered a treatment of last resort but a potential first-line treatment when a rapid clinical response is essential in severely ill patients (e.g., those with active suicidal ideation, malignant catatonia, or a compromised medical condition related to depression such as dehydration or malnutrition), when the patient has a history of a positive response to ECT, or when the patient and family request ECT over other treatment options. ECT generally exerts its antidepressive effects more rapidly that pharmacotherapy does, and recent research has confirmed a rapid resolution of suicidal ideation with ECT (Kellner et al. 2005; Patel et al. 2006). Beale and Kellner (2000) argued that the use of ECT after multiple failed medication trials does not take into account the tolerability and efficacy of modern ECT and may lead to needless suffering on the part of the patient. They pointed out that antidepressive treatment algorithms place ECT as a tertiary treatment (e.g., Rush and Thase 1997) instead of recommending that ECT practitioners be consulted early in the treatment process to determine whether ECT would be appropriate therapy. Surveys show that patients who have received ECT rate it as a highly effective treatment (Parker et al. 2001), and that 85% of patients who have received ECT would agree to a second course of ECT if needed (Bernstien et al. 1998). ECT-related relief of depressive symptoms has also been associated with

long-term improvements in health-related quality of life, an increasingly important outcome measure in medical research (McCall et al. 2006).

Predictors of Response

Clinical predictors of response to ECT have not been consistent across studies. Potential positive predictors of response include increasing age (Dombrovski et al. 2005; O'Connor et al. 2001) and the presence of psychotic or catatonic symptoms (Birkenhager et al. 2005; Buchan et al. 1992; Petrides et al. 2001). Several studies have reported that patients with longer current episodes of depression (Dombrovski et al. 2005; Prudic et al. 1996) or personality disorders (e.g., borderline personality disorder) (Feske et al. 2004; Parker et al. 2001) are less likely to respond to ECT. Patients with depression complicated by dysthymia (i.e., double depression) appear to respond to ECT to the same extent that patients without dysthymia do (Prudic et al. 1993). Attempts to link subtypes of depression (e.g., melancholic vs. atypical, unipolar depression vs. depression associated with bipolar disorder) to the likelihood of ECT response have generally failed to reveal differences. However, response by session 3 of ECT may predict long-term efficacy in relieving depression (Tsuchiyama et al. 2005).

Medication resistance also has correlated with a failure to respond to ECT. Patients who had failed to respond to treatment with one or more antidepressants before receiving ECT responded less favorably to ECT than did patients who had not failed to respond to medication (Devanand et al. 1991; Dombrovski et al. 2005; Prudic et al. 1990; Sackeim et al. 1990). This was true for resistance to the heterocyclic antidepressants but not to the selective serotonin reuptake inhibitors (SSRIs) or monoamine oxidase inhibitors (MAOIs) (Prudic et al. 1996).

To date, the most consistent biological marker for ECT response has been increased frontal delta activity (i.e., postictal depression) shown on the electroencephalogram (EEG) after ECT (Mayur 2006; Sackeim et al. 1996), which is associated with decreased cerebral blood flow in the immediate postictal period (Nobler et al. 1994). More sophisticated methods of EEG analysis (e.g., nonlinear analysis) may hold promise in helping to discern electroencephalographic predictors of the antidepressive efficacy of ECT (Mayur 2006).

Coffey et al. (1989) described a greater number of structural abnormalities observed on magnetic resonance imaging (MRI) scans of the brain (e.g., deep white matter, basal ganglia, and periventricular hyperintensities) in elderly depressed patients referred for ECT, compared with age-matched control subjects. These preexisting structural brain abnormalities may predispose elderly depressed patients to a less favorable response to ECT (Hickie et al. 1995; Steffens et al. 2001), although case reports indicate that ECT may be helpful in the treatment of depression after a stroke (Currier et al. 1992).

Mania

Early anecdotal reports as well as more recent case studies suggest that ECT is beneficial in the treatment of mania associated with bipolar disorder and delirious mania (Fink 2001b, 2006). ECT also has been shown to be effective in patients with treatment-resistant mixed mood disorders (Gruber et al. 2000). Given the benefit of anticonvulsant medications in treating mania and the evidence that ECT may exert its therapeutic effect by raising the seizure threshold (Sackeim 1999), we have a theoretical basis for assuming that ECT is effective in the treatment of mania. Since 1970, several retrospective studies have confirmed the efficacy of ECT in patients with mania, with approximately two-thirds of patients showing marked clinical improvement (Mukherjee et al. 1994). In a prospective, controlled trial, Small et al. (1988) compared the efficacy of ECT with that of lithium in the treatment of mania. Patients who received ECT improved more during the first 8 weeks of treatment than did patients who received lithium. Nevertheless, after 8 weeks of treatment, ECT and lithium were comparable in efficacy. In addition, patients with mixed symptoms of depression and

mania responded particularly well to ECT. Catatonia may be especially common in patients with bipolar disorder, and this represents another scenario in which ECT may offer advantages in efficacy and rapidity of response versus pharmacotherapy (Taylor and Fink 2003). Challenges specific to treating mania with ECT include the following:

- Concomitant use of anticonvulsants, which may interfere with seizure induction in ECT
- Reports of prolonged seizures and delirium when ECT is given with lithium (Sartorius et al. 2005), although other authors have reported safe coadministration of ECT and lithium (Dolenc and Rasmussen 2005)
- Decreased likelihood that manic (vs. depressed) patients will voluntarily consent to ECT treatment

Despite a rapid increase in studies evaluating alternative antimania medications, including newer anticonvulsants and the atypical antipsychotics, there is a lack of research comparing the potential benefits of ECT in the acute and maintenance treatment of bipolar disorder (Fink 2001b; Keck et al. 2000). This is regrettable given the advantages of ECT as a true mood stabilizer that can effectively treat both the manic and the depressed phases of the illness. ECT has been given safely to children with intractable mania (Hill et al. 1997) and to patients with dementia and comorbid mania (McDonald and Thompson 2001). ECT also may have an important role in the treatment of mania during pregnancy, given the potential teratogenic effects of many anticonvulsant medications as well as the potential harm to both the mother and the fetus from a prolonged affective episode.

Controversy persists over whether unilateral ECT is as effective as bilateral ECT in the treatment of mania. Unfortunately, studies comparing unilateral and bilateral ECT in the treatment of mania have reported neither the amount of electrical charge used nor the percentage by which the electrical stimulus exceeded the seizure threshold. Daly et al. (2001) compared 228 patients with bipolar disorder or unipolar depression who were randomly assigned to ECT conditions that differed in electrode placement and stimulus intensity. They found that the bipolar patients had a rapid response to both unilateral and bilateral ECT and did not differ from the unipolar patients in either the rate of response or the response to unilateral or bilateral ECT. ECT also has been shown to be efficacious in the treatment of mixed mania (Ciapparelli et al. 2001). Future research is certainly needed to clarify the role of ECT in the treatment of mania, although clear evidence indicates that ECT is an effective treatment and should be included in any algorithm of therapy for treatment-resistant or severely disabling mania.

Schizophrenia

With the introduction of clozapine and the atypical antipsychotics, ECT has become a third-line treatment for schizophrenia, although it continues to have an important role in the treatment of an acute psychotic episode, catatonic schizophrenia, and neuroleptic malignant syndrome. Although the mechanism of action of ECT in treating psychosis has received much less attention than the mechanism of its antidepressive effects, a possible mechanism of ECT's antipsychotic effects has been inferred from the therapeutic action of ECT in patients with phencyclidine-induced psychosis (Dinwiddie et al. 1988). One of the major actions of phencyclidine and related drugs (e.g., ketamine) is the blocking of open channels for NMDA receptors. Phencyclidine-induced channel blocking is voltage dependent and long lived, with the ion channel closing around the phencyclidine molecule (MacDonald et al. 1991). Relief of channel blocks requires NMDA ion channels to open at depolarized membrane potentials (Huettner and Bean 1988). Thus, neuronal membrane depolarization and glutamate receptor binding are important for allowing phencyclidine to exit the channel. Although it is not certain that blocking of NMDA channels causes phencyclidine-induced psychosis, it is interesting that ECT-induced seizures have the requisite effects to relieve the channel block. During a seizure, neurons depolarize (via synaptic excitation and action potential firing) and glutamate is released at synapses. These events together would be expected to relieve phencyclidine-induced blockage and could provide a rationale for the effectiveness of ECT. As a corollary, this mechanism would also lead to the prediction that the use of ketamine for anesthesia during ECT should be associated with a low

incidence of ketamine-induced psychosis.

Fink and Sackeim (1996) reviewed the use of ECT in the treatment of schizophrenia and cautiously noted that most studies examining the efficacy of ECT in treating schizophrenia do not meet current standards for scientific methodology. Nonetheless, the authors concluded that ECT is a highly effective treatment for psychosis and that it should be considered, particularly for patients with schizophrenia and an initial psychotic episode, symptoms of agitation, increased psychomotor activity, delirium, or delusions. The authors also concluded that ECT is effective in treating schizophrenia when catatonia, prominent affective symptoms, or positive symptoms of psychosis (e.g., hallucinations) are present. They speculated that the use of ECT early in the course of schizophrenia may decrease the progressive, debilitating effects of the illness.

ECT combined with neuroleptics has been shown to be more effective than ECT or neuroleptics alone in treating schizophrenia (Friedel 1986; Gujavarty et al. 1987; Klapheke 1993; Sajatovic and Meltzer 1993). A recent meta-analysis of the four most methodologically sound studies of ECT augmentation to antipsychotics for treating schizophrenia concluded that ECT offers a modest but significant benefit (equivalent to 5 points on the Brief Psychiatric Rating Scale) compared with neuroleptic therapy alone (Painuly and Chakrabarti 2006). The effects are apparent in the first several weeks of treatment but appear to diminish with prolonged treatment. Interestingly, all of these studies were conducted in India, where the use of ECT to treat schizophrenia appears to be more common than it is in the United States. Notably, open-label studies and case studies suggest that ECT may be safe and helpful in combination with clozapine, another treatment typically reserved for more treatment-refractory illness (Havaki-Kontaxaki et al. 2006). ECT combined with neuroleptic therapy may also be effective in the management of aggressive behavior in patients with schizophrenia (Hirose et al. 2001) and for maintenance treatment of schizophrenia (Chanpattana et al. 1999b).

The recommendations of the American Psychiatric Association Task Force on Electroconvulsive Therapy (2001) state that ECT is an effective treatment for schizophrenia in the following clinical conditions: 1) during acute onset of symptoms, 2) when the catatonic subtype of schizophrenia is present, and 3) when there is a history of a positive response to ECT. Not surprisingly, patients with an affective component (i.e., schizoaffective patients) also respond more favorably to ECT than do schizophrenic patients without subsyndromal affective disorders. In addition, ECT represents a potentially life-saving intervention for patients with neuroleptic malignant syndrome that does not respond to more conservative treatments (e.g., supportive care or pharmacotherapy). Clearly, there is a need for further research related to the role of ECT in treating schizophrenia.

1994). Many of the other medications, including atypical antipsychotics, benzodiazepines, and antidepressants, have less clear effects on the fetus. Yet the complications of untreated or partially treated bipolar disorder endanger both the mother and the fetus and include poor compliance with neonatal care, impaired judgment, substance abuse, poor nutrition and self-care, and depression with suicide attempts (Miller 2001).

STIMULUS DOSING IN ECT FOR TREATMENT OF DEPRESSION

Questions about the proper management of the electrical stimulus have been central to the science and practice of ECT since the inception of the treatment. Cerletti and Bini modeled ECT on the success of pharmacologically induced convulsive therapy and assumed that the stimulus should be convulsive. Interestingly, the first ECT session in 1938 involved two subconvulsive stimulations before Cerletti and Bini increased the stimulus intensity to produce a convulsion (Endler 1988). Thus, the first ECT session was a "titrated" ECT session involving the serial application of increasing stimulus intensities passing from the subconvulsive range through the convulsive threshold. Issues in stimulus dosing that have been considered since that time include the following:

- Whether the stimulus should be subconvulsive or convulsive
- What the optimal stimulus waveform is
- If a convulsive stimulus is desired, to what degree the stimulus intensity should be in excess of the convulsive threshold
- Which physiological parameters, if any, provide useful feedback to continuously refine stimulus dosing throughout the ECT course

Convulsive, Subconvulsive, and Sham Stimulation

The use of nonconvulsive electrical stimulation to treat psychiatric disorders preceded the introduction of ECT by decades. Most of the treatments involved administering static electricity to parts of the body including but not limited to the head (Grover 1924). The availability of commercial ECT devices did not lead to the immediate replacement of subconvulsive stimulation with convulsive stimulation. Instead, some practitioners used the devices to deliver lengthy (several minutes long) subconvulsive cranial stimulation. However, it became clear that subconvulsive stimulation was associated with a *poorer* outcome than conventional psychotherapy in psychoneurotic patients, and the practice of treating patients with subconvulsive stimuli decreased (Hargrove et al. 1953). Now, many years later, the use of rapid-rate transcranial magnetic stimulation (rTMS) has re-opened the question of whether subconvulsive stimuli are an effective treatment for depression; these data are reviewed in a later section (see "Transcranial Magnetic Stimulation and Subconvulsive Stimuli").

The elements of modified ECT (including muscle relaxation and general anesthesia) were described early in the history of ECT. The wide-scale adoption of these modifications raised new questions as to whether seizure is central to the antidepressive efficacy of ECT or whether anesthesia alone would be just as effective. The Northwick Park trial (Johnstone et al. 1980) and the Leicestershire trial (Brandon et al. 1984) are examples of two "sham" ECT studies in which anesthesia alone was compared with real ECT. It was convincingly demonstrated that real ECT is more efficacious, especially for the most severe forms of depression (Brandon et al. 1984; Johnstone et al. 1980). The efficacy of ECT was clearly linked to the production of a seizure. Neither the use of anesthesia alone without the electrical stimulus nor the use of subconvulsive stimuli appears to have real merit in the treatment of depression.

Stimulus Waveform

Given that a convulsive stimulus is necessary for the antidepressive effects of ECT, a nearly infinite number of variations are available for formulating the stimulus waveform. The earliest ECT devices delivered a sinusoidal stimulus. Other waveforms available on early ECT devices included the

"chopped" sine wave, the unidirectional pulse square wave, and the alternating brief-pulse square wave. Although some investigators had a suspicion that sine wave stimuli might produce slightly better antidepressive effects than did brief-pulse stimuli, that suspicion was mitigated by a randomized study showing that sine wave ECT produced more memory side effects than brief-pulse ECT, irrespective of the placement of the stimulating electrode (R. D. Weiner et al. 1986). This finding of greater cognitive side effects with sine wave ECT was recently replicated in an efficacy study using a prospective cohort design, which showed that compared with brief-pulse stimulation, sine wave stimulation was associated with a slowing of reaction time that persisted for at least 6 months after ECT (Sackeim et al. 2007). The more severe cognitive side effects produced by sinusoidal stimuli may be explained by the slower rise time for each sine wave cycle as compared with the brief-pulse cycle. Consequent to the slower rise time, much of the sine wave stimulus is subconvulsive and thus presumably adds nothing to the therapeutic effect of ECT, adding only to cognitive side effects. The steep rise in the brief-pulse waveform allows for the entire stimulus to be above the convulsive threshold (suprathreshold). Because much of the sine wave stimulus is nonproductive, being in the subconvulsive range, it would be predicted that brief-pulse stimuli would be more efficient, requiring a stimulus of smaller magnitude to produce a seizure. *Standard* brief-pulse stimuli are defined by pulse duration of 1–2 milliseconds, while *ultrabrief*-pulse stimuli are defined by pulse duration of 0.25–0.50 milliseconds.

In 1980, Weiner showed that standard brief-pulse stimuli could provoke a seizure with only one-third of the energy required with sine wave stimuli (Weiner 1980). In the last decade, standard brief-pulse ECT devices replaced sine wave devices in the United States (Farah and McCall 1993). New devices using ultrabrief-pulse stimuli have the advantage of improving the efficiency of seizure induction. Abrams (2002) estimated that it takes only about 0.25 milliseconds to initiate neuronal depolarization, and wider pulse widths are inefficient and waste electrical charge. The total energy output of these ultrabrief-pulse modalities is the same as the total energy output of the standard brief-pulse widths; thus, as the stimulus pulse widths are shortened, the stimulus trains are lengthened. Ultrabrief-pulse widths may have an advantage because shorter pulse widths and longer pulse trains have been shown to elicit seizures with a smaller electrical charge and therefore may have fewer cognitive side effects (Sackeim et al. 2001b). Similarly, decreasing the frequency of pulses with a corresponding lengthening of the stimulus train will improve the efficiency of seizure induction (Kotresh et al. 2004).

Magnitude of the Stimulus Dose

The consensus regarding the need for convulsive (as opposed to subconvulsive) stimuli and brief-pulse waveforms would seem to make stimulus dosing in ECT a straightforward process, except for the question of the degree to which the stimulus should exceed the convulsive threshold. For years, ECT practitioners were satisfied that the answer to this question was found in the work of Ottosson (1962), who compared routine ECT with ECT modified by pretreatment with intravenous lidocaine. He found that seizures induced by lidocaine-modified ECT were shorter than those induced by routine ECT and observed an inverse relationship between seizure duration and antidepressive effect. From this work, it was widely accepted that stimulus doses producing seizures lasting at least 25 seconds have an antidepressive effect (American Psychiatric Association Task Force on Electroconvulsive Therapy 1978).

Initially, ECT was administered using bilateral (typically bitemporal) electrode placement. In 1949, Goldman introduced right-unilateral ECT and placed stimulating electrodes over the right hemisphere rather than the mesial temporal lobes in an attempt to decrease the direct stimulation of language areas and decrease cognitive side effects. Although right-unilateral ECT was associated with fewer cognitive side effects, most studies showed that bilateral ECT had a marked therapeutic advantage over unilateral ECT for depression (d'Elia and Raotma 1975).

The clinical wisdom that bilateral ECT was more effective than right-unilateral ECT in treating

depression came into question with the groundbreaking work of Sackeim's research group. Sackeim et al. (1993) reported that when the magnitude of the electrical stimulus was just barely above the convulsive threshold, ECT with right-unilateral electrode placement was not efficacious, despite the production of electrographic seizures typically in excess of 25 seconds. However, as the electrical dose was progressively increased, response rates in right-unilateral ECT improved significantly and approached those of bilateral ECT. In contrast, bilateral ECT was fully efficacious with stimuli minimally above or 2.5 times the seizure threshold, but excess memory side effects accrued at the higher stimulus dose.

The dose–response relationship of right-unilateral ECT holds true to the extent that the stimulus exceeds the convulsive threshold for a given patient, but is not related to the absolute magnitude of the stimulus dose. The efficacy of right-unilateral ECT follows a nearly linear relationship to the degree that the stimulus dose exceeds the seizure threshold, at least through 12 times the seizure threshold (McCall et al. 2000). This relationship is analogous to the pharmacological treatment of depression with tricyclic antidepressants: serum blood levels are more important than the absolute oral dose in determining both efficacy and side effects.

These findings led to the following conclusions:

- With standard brief-pulse stimulation delivered with right-unilateral electrode placement, the stimulus should be substantially above the convulsive threshold in order to ensure the effectiveness of ECT.
- With standard brief-pulse stimulation delivered with bilateral electrode placement, the stimulus should not be excessively above the convulsive threshold, in order to avoid undue cognitive side effects.

The convulsive threshold varies by a factor of at least 40 in large patient samples; thus, the mean threshold for a group of patients is useless for individual cases (Sackeim et al. 1991). It is clear that the convulsive threshold is related to age, sex, race, choice of stimulating electrode placement, and, perhaps, cranial dimensions (Chung 2006; Colenda and McCall 1996; McCall et al. 1993b; Sackeim et al. 1991). Still, these factors predict only a small amount of the variance in the convulsive threshold, and statistical models to predict the convulsive threshold, including age-based dosing approaches, fare poorly (Colenda and McCall 1996; Tiller and Ingram 2006).

Seizure Morphology

The report of Sackeim et al. (1993) that threshold right-unilateral ECT produced seizures of 25 seconds or longer without antidepressive efficacy cast into doubt the clinical wisdom that the stimulus dose was therapeutic if the electrographic seizure lasted at least 25 seconds. Investigators have sought to find a physiological marker of treatment adequacy to replace seizure duration. The most promising candidate is seizure morphology. Ottosson (1962) reported that lidocaine changed the shape of ECT seizures and affected their duration, although the first finding is largely overlooked. Lidocaine-modified seizures, in addition to being less efficacious than standard ECT seizures, were characterized by loss of spike activity and poor postictal suppression.

This finding has been extended by evidence that seizure morphology varies with ECT techniques. That is, greater seizure intensity correlates with ECT techniques that progress from lower efficacy (with right-unilateral electrode placement and low stimulus intensity) to higher efficacy (with bilateral placement and high stimulus intensity) (Krystal et al. 1993). Electrode placement and stimulus intensity have independent and additive effects on seizure morphology. Seizures of greater intensity are characterized by higher peak ictal amplitudes, greater stereotypy of the ictal discharge, greater symmetry and coherence between the left and right cerebral hemispheres, and more profound postictal suppression. Preliminary evidence suggests that greater seizure intensity is predictive of a greater likelihood of response and/or faster response (McCall et al. 1995; Nobler et al. 1993).

The natural extension of this reasoning leads to the hope that seizure morphology could guide

decisions about stimulus intensity as the course of ECT progresses. For example, if seizure intensity is poor in the middle of the treatment course, then the treatment technique should be changed (by switching electrode placement and/or increasing the stimulus intensity) in order to optimize the clinical outcome. Manufacturers of ECT devices now incorporate automated measures of seizure intensity onto the ECT chart recorder, and the accompanying owner's manual instructs the practitioner to increase the stimulus intensity if the seizure morphology appears to be degraded. The unstated implication is that poor seizure morphology is a problem and that increasing the stimulus intensity will fix the problem. This instruction might have merit if stimulus intensity were the primary determinant of seizure morphology, but other factors, such as age, baseline convulsive threshold, and other intrinsic patient factors likely play an equal role in determining seizure expression (McCall et al. 1996, 1998). For example, greater seizure durations coupled with greater seizure regularity as shown by electroencephalography at the second ECT session are predictive of a better antidepressive outcome at the conclusion of the ECT course, and this relationship is independent of the choice of stimulus electrode placement (Rosenquist et al. 2007).

Poor seizure morphology (e.g., in older patients with high seizure thresholds) is little influenced by increasing the stimulus intensity above 2.5 times the seizure threshold. Therefore, it is premature to recommend stimulus dosing on the basis of seizure morphology. The importance of seizure morphology in predicting clinical outcome is far from being understood, and more work is needed to make it a practical tool for governing ECT technique. Peak heart rate has been proposed as an alternative physiological measure of treatment adequacy, with higher heart rates perhaps indicating better clinical outcomes (Swartz 2000). Again, this approach has yet to be widely accepted.

Integrating the Science of Stimulus Dosing With the Choice of Electrode Placement

Estimating the Convulsive Threshold

The recent advances in knowledge pertaining to stimulus dosing lead to the conclusion that standard brief-pulse, right-unilateral ECT should be initiated with a stimulus known to be at least five times the seizure threshold, while standard brief-pulse, bilateral ECT should be initiated with a stimulus about 50% above the seizure threshold. Choosing between these two strategies requires consideration of both efficacy and side effects. An indirect comparison was made by Stoppe et al. (2006) in a study of older depressed patients randomly assigned to receive fixed high doses of either right-unilateral ECT (n = 17) or bilateral ECT (n = 22). Although the failure of this study to dose according to a known seizure threshold makes the cognitive findings difficult to evaluate, it did show similar remission rates with right-unilateral ECT (88%) and bilateral ECT (68%), suggesting that efficacy need not be compromised by choosing right-unilateral placement.

McCall et al. (2000) conducted the first randomized comparison of low-dose (1.5 times the seizure threshold) bilateral ECT (n = 37) versus high-dose (8 times the seizure threshold) right-unilateral ECT (n = 40). Again, depression remission rates were not significantly different with right-unilateral electrode placement (60%) versus bilateral placement (73%), and memory effects were likewise similar. This study can be criticized for having insufficient power to detect small but meaningful effects. That concern was addressed in a subsequent study by Haskett et al. (2007) contrasting 339 patients randomly assigned to receive either standard brief-pulse, right-unilateral ECT administered at 6 times the seizure threshold or bilateral ECT administered at 1.5 times the seizure threshold. Although differences between the treatments' antidepressive effects were again indistinguishable, the extent of autobiographical memory loss was greater in the bilateral group. This study solidifies the position of high-dose right-unilateral ECT as the preferred initial strategy. Even if patients fail to respond to an initial approach using right-unilateral electrode placement, increasing the stimulus intensity with right-unilateral ECT is associated with a subsequent antidepressive response equal to

the response obtained after switching to bilateral ECT, with fewer cognitive side effects (Tew et al. 2002).

The bulk of the evidence thus suggests that it is desirable to set the stimulus dose as a proportion of the convulsive threshold; the convulsive threshold of each patient should be known, preferably by measuring convulsive threshold early in the ECT course. The most accurate means of measuring the convulsive threshold for a given patient is empirical observation: giving intentionally subconvulsive stimuli at the first treatment; then, in the same session, administering successively larger stimuli until a seizure is produced. This stimulus "titration" technique defines the convulsive threshold for each patient. This approach applies to right-unilateral and bilateral electrode placement.

If ECT practitioners agree with the above reasoning and use this stimulus dosing technique, they should ascertain the convulsive threshold at the first ECT session. However, some ECT researchers have argued against titration of stimulus doses with unilateral ECT and instead have encouraged practitioners to use fixed high doses of unilateral ECT (Abrams 2002) or fixed moderate doses of bilateral ECT (Kellner 2001). In fact, a survey of ECT practitioners in 1993 showed that only a minority performed titration of the stimulus dose (Farah and McCall 1993). The reasons for this are unclear, but possible explanations include concerns that 1) the subconvulsive stimulation inherent in stimulus titration might be medically dangerous, 2) subconvulsive stimulation might add to memory side effects, or 3) production of a barely suprathreshold seizure with right-unilateral placement would constitute ineffective treatment, thus rendering the first treatment a wasted effort.

It is true that subconvulsive stimulation transiently slows the heart rate, and that if subconvulsive stimulation is given to patients who have received a β-blocker and no anticholinergic drug, there is risk of substantial asystole (McCall et al. 1994). On the other hand, atropine pretreatment eliminates this risk. The possibility of excess acute cognitive side effects with subconvulsive stimuli has been examined and discounted (Prudic et al. 1994). The possibility of a sluggish antidepressive response when stimulus doses are titrated to a level moderately above the seizure threshold in combination with right-unilateral electrode placement, however, is a real concern. A prospective, randomized trial in elderly depressed subjects showed that a titrated, moderately suprathreshold dosing strategy with right-unilateral electrode placement produced a slower antidepressive response than did fixed high stimulus doses with right-unilateral electrode placement (McCall et al. 1995). Similar results were seen in a naturalistic comparison of young adults receiving titrated, right-unilateral ECT at 2–3 times the seizure threshold versus right-unilateral ECT at a fixed high dose (Ward et al. 2006). Interpretation of these studies is made more difficult by differences between the treatment groups (titrated vs. fixed doses; moderate vs. high doses). At the very least, however, it is clear that different dosing strategies affect the antidepressive outcome of right-unilateral ECT, even when the doses being compared are substantially above the convulsive threshold.

Alternatives to Estimating the Convulsive Threshold

Abrams (2002) suggested that the most efficient method of administering right-unilateral ECT is to use 100% of the maximum device capacity and a pulse width of 0.25–0.50 milliseconds and recommended changing to bilateral ECT if the patient does not improve sufficiently. However, insufficient data support the routine use of ultrabrief-pulse widths (Fink 2002), and the use of stimulus titration to establish a dose relative to the seizure threshold would potentially decrease cognitive problems while ensuring an adequate seizure (Rasmussen 2002). Alternatively, twice-weekly bilateral ECT could be initiated using the half-age method (Abrams 2002). In the half-age method, the age of the patient is divided by 2; the resulting number is the percentage of the device's maximal output with which the patient is first treated (e.g., a 50-year-old would be treated at 25% of the machine's maximal output). Kellner (2001) recommended an alternative fixed-dose strategy that involves starting with 75% of maximal output for right-unilateral ECT and 30%–60% of maximal output for bilateral ECT.

Our recommendations for stimulus dosing are made with the following two caveats:

1. Recommendations can be made only in regard to treating major depression, as it is unknown whether dosing strategies for patients with other diagnoses should be the same as those for treating depression.
2. Dosing recommendations can be made only in the context of the chosen electrode placement and the patient's clinical condition.

It is clear that a supraconvulsive stimulus is necessary to obtain an antidepressive effect with right-unilateral ECT. It is unclear whether any supraconvulsive stimulus would have equivalent antidepressive efficacy with bilateral electrode placement, but a stimulus of at least 2.5 times the convulsive threshold is required with right-unilateral ECT in most patients.

Choosing an Electrode Placement and Stimulus Dose

Those patients with the most serious complications of major depression (i.e., active suicidal behavior in the hospital, catatonia, or food refusal) merit an approach most likely to yield quick antidepressive results. In such circumstances, bilateral ECT with a relatively high fixed stimulus dose (e.g., 50% of the machine's maximal output) could be justified; stimulus dose titration would not be required because concern about cognitive side effects becomes a purely secondary issue, based on the severity of the patient's clinical status. However, whether fixed high-dose right-unilateral ECT could provide an equally fast and effective response needs to be examined.

In contrast, a depressed patient in whom medication has failed but who is otherwise not in urgent need of treatment may be an appropriate candidate for right-unilateral ECT at 5–6 times the seizure threshold, especially if cognitive side effects are a concern or if the patient is being treated in an outpatient setting. The patient can start with right-unilateral ECT and after five or six treatments change to bilateral ECT if he or she has not had an adequate response. Other special situations favoring titrated right-unilateral ECT include the treatment of depressed patients with comorbid dementia or other neurological conditions such as Parkinson's disease. The treatment of these patients should minimize even transient memory side effects and may include starting at a very conservative unilateral dose (i.e., 3.5 times the seizure threshold) and increasing the dose as tolerated.

Other dosing strategies, such as titrated bilateral or fixed high-dose right-unilateral ECT, occupy the strategic middle ground between titrated right-unilateral and fixed-dose bilateral ECT for patients whose condition is of intermediate acuity. One promising area of research is the development of bifrontal ECT, which has the potential for providing the efficacy of bilateral ECT with a cognitive side-effect profile similar to that of right-unilateral ECT. In bifrontal ECT, the electrodes are placed 5 cm above the lateral angle of each orbit in a line parallel to the sagittal plane in order to directly stimulate the frontal lobes, which have been implicated in the pathology of major depression (Nobler et al. 2000) and response to ECT (Nobler et al. 1993). Compared with bilateral and right-unilateral ECT, bifrontal ECT would potentially spare the temporal lobes and decrease cognitive side effects. Preliminary research has shown that bifrontal ECT is comparable in efficacy to bilateral ECT, and preliminary evidence indicates that bifrontal ECT (at either the seizure threshold or 1.5 times the seizure threshold) has fewer cognitive side effects than bilateral ECT (Bailine et al. 2000; Lawson et al. 1990; Letemendia et al. 1993; Ranjkesh et al. 2005). A retrospective chart review of 76 patients found that bilateral ECT was more effective than bifrontal ECT with modestly increased side effects (Bakewell et al. 2004).

In a study comparing right-unilateral and bifrontal ECT, Heikman et al. (2002) randomly assigned 24 depressed patients to receive high-dose right-unilateral ECT (at 5 times the seizure threshold), moderate-dose right-unilateral ECT (at 2.5 times the seizure threshold), or low-dose bifrontal ECT (just above the seizure threshold). Among the 22 patients who completed the study, depression remitted in 7 of 8 patients (88%) treated with high-dose right-unilateral ECT, compared with just 3 of

7 patients (43%) each in the groups treated with moderate-dose right-unilateral and low-dose bifrontal ECT (the difference was not statistically significant). All three groups were similar in terms of cognitive changes measured by the Mini-Mental State Exam (Folstein et al. 1975), it is difficult to know exactly when bifrontal ECT should be used in a clinical ECT service, because the research is lagging behind clinical practice (C. K. Loo et al. 2006). A multisite study funded by the National Institute of Mental Health is under way using more sophisticated cognitive testing and outcome measures to determine whether bifrontal ECT is a viable alternative to high-dose right-unilateral or bilateral ECT.

ECT TECHNIQUES

Pretreatment Medical Evaluation

Although no medical condition is an absolute contraindication for ECT, several clinical conditions may increase the risk of complications from ECT:

- Recent myocardial infarction or unstable cardiac conditions
- Any illness that increases intracranial pressure (e.g., brain tumor)
- Recent cerebral infarction, particularly hemorrhagic infarction
- Aneurysm or vascular malformation
- American Society of Anesthesiology physical status classification level 4 or 5
- Severe pulmonary disease

When treating high-risk patients with ECT, clinicians must evaluate the effects of ECT on cerebral and cardiac physiology and review data from the extant ECT literature to help develop individual risk–benefit ratios (American Psychiatric Association Task Force on Electroconvulsive Therapy 2001; Applegate 1997; Bader et al. 1995; Krystal and Coffey 1997; Weisberg et al. 1991; Zwil et al. 1992). All patients should undergo a thorough medical and neuropsychiatric review before beginning ECT. Particular emphasis should be placed on diseases affecting the CNS and the cardiovascular system. The pre-ECT evaluation should include a physical examination, detailed neurological examination, mental status examination, medical history, and review of systems. The patient's mental status should be evaluated before initiation of ECT and monitored closely before administration of ECT at every session thereafter.

The baseline screening should include some basic laboratory tests (blood count and electrolytes) and an electrocardiogram. Clinicians should obtain a chest X ray for patients with pulmonary disease. Spine films should be considered for patients with a history of back pain, positive findings on physical examination, or medical conditions that may affect the skeletal system. Even patients who are recovering from surgery to repair a broken hip can be safely treated with ECT if appropriate doses of succinylcholine are used to ensure adequate relaxation. The greatest risks for fractures are in the recovery room if the patient has significant postictal confusion and agitation, and during the acute ECT course when patients, particularly the elderly and those with Parkinson's disease, are at increased risk for falling.

Information obtained about the patient's neuropsychiatric history should include the following:

- Complications from anesthesia (including a family or personal history of malignant hyperthermia)
- Dementia or other neurological disease
- Any symptoms on neurological examination suggestive of increased intracranial pressure (e.g., severe headaches, new-onset incontinence, or gait ataxia) or primary neurological disease (e.g., lateralizing neurological deficits)

Based on the patient's examination, brain imaging may be ordered before ECT. Some (Kellner 1996) have called for a reevaluation of the common practice of obtaining brain imaging for all patients prior to ECT. Kellner argues that with proper screening, the number of patients with significant CNS findings

on imaging who have normal neurological examination findings is very low, and the expense of routine screening is high.

The clinician also must assess the patient's cardiovascular status, including evidence for dyspnea on exertion, angina, orthopnea, or conditions that might increase the risk of coronary artery disease (e.g., hyperlipidemia, hypercholesterolemia, poorly controlled hypertension, obesity, or diabetes). ECT in some ways represents a cardiac stress test, with an abrupt rise in the heart rate and blood pressure occurring after the stimulus. Therefore, one of the most important screens to determine whether a patient can tolerate ECT is accurately assessing exercise tolerance. This can be accomplished by asking questions such as the number of stairs a patient can climb without becoming short of breath. Patients with evidence of coronary artery disease can be screened with a relatively inexpensive treadmill test establishing a peak heart rate of approximately 120. However, ECT patients with severe depression are typically sedentary, elderly, and often unable to tolerate even minimal physical activity. Many would be unable to complete a treadmill test; more expensive tests, such as a persantine thallium stress test, can be substituted when appropriate.

Establishing a working relationship with a cardiologist is an essential part of developing an ECT service. Often the consulting cardiologist is asked to "clear a patient for ECT" without understanding exactly what effects ECT would have on the patient's cardiovascular system. A significant acute risk to the patient undergoing ECT is the potential for a cardiovascular event, and optimizing the management of cardiovascular disease before and during ECT can decrease this risk. Inviting the consulting cardiologist to observe the ECT procedure and including the cardiologist in discussions with both the patient and the family help ensure that all the involved parties make informed decisions regarding the relative risk–benefit ratio of the procedure.

Finally, informed consent should be obtained from all patients before ECT. Patients deemed to be incompetent may require the appointment of a legal guardian for consent. States vary in the legal regulations governing the use of involuntary ECT.

Medications Used During ECT

Patients should have nothing by mouth the night before their treatment and should limit the number of medications, and water needed to swallow the medications, on the morning of ECT to cardiac medications (except lidocaine), pulmonary medications (except theophylline), and glaucoma medications (except cholinesterase inhibitors, e.g., echothiophate). Given that the patient's oral intake is restricted, clinicians should also consider withholding any diuretics until after the treatment depending on the patient's cardiac status.

It is recommended that theophylline be discontinued and inhalers substituted and brought to the ECT suite to be given immediately prior to the treatment. Theophylline has been associated with status epilepticus during ECT (Devanand et al. 1988). A case review of ECT use in patients with asthma was

ECT. If difficulty arises in eliciting seizures, decreasing the dose of the anticonvulsant can be considered. Lunde et al. (2006) recently summarized reports of ECT use in persons with epilepsy and recommendations for its safe use in this population.

In the past, it was recommended in the United States that all psychotropic medications be discontinued prior to beginning ECT. In other countries, it is common practice to continue using antidepressants during ECT (Royal College of Psychiatrists 1995). Available data are mixed regarding the use of antidepressants concurrently with ECT. Previous studies in the 1950s and 1960s suggested a possible better response to ECT in patients receiving tricyclic antidepressants (Dunlop 1960; Kay et al. 1970; Sargant 1961). Later studies also suggested that the response to ECT may be superior when combined with tricyclic antidepressant use but not with the use of SSRIs (Lauritzen et al. 1996; Nelson and Benjamin 1989). Further research is needed to clarify this issue. When neuroleptic agents are necessary to control agitation or psychotic symptoms, a high-potency neuroleptic or an atypical antipsychotic medication is preferable to minimize any hypotension that may develop during ECT. Antipsychotics are generally continued during ECT treatment of persons with primary psychotic disorder (e.g., schizophrenia or schizoaffective disorder).

Concerns have been raised over whether MAOIs can be used safely with anesthesia. Although some clinicians still recommend caution and a 7- to 14-day washout period before proceeding with ECT, extensive reported experience with MAOIs and ECT has documented few significant problems (American Psychiatric Association Task Force on Electroconvulsive Therapy 2001; Dolenc et al. 2004).

Lithium usually is discontinued at least 48 hours before ECT because a potentially increased risk of delirium and cognitive impairment during ECT has been reported with its use (Ahmed and Stein 1987; Small 1990; Small et al. 1980). In more recent studies, however, the use of lithium was not associated with increased confusion in acute (Jha et al. 1996; Mukherjee 1993) or maintenance (J. T. Stewart 2000) ECT.

Benzodiazepines can interfere with the induction of a seizure during ECT, thereby decreasing the efficacy of the treatments (Jha and Stein 1996). As a result, benzodiazepine doses should be reduced to the lowest possible or eliminated before ECT. Patients taking benzodiazepines should be receiving a stable dose for 24–48 hours before ECT in order to reduce the risk of prolonged seizures or status epilepticus during ECT. Flumazenil, a competitive benzodiazepine antagonist, at a dose of 0.4–0.5 mg, has been effective in maintaining seizures without decreasing efficacy in patients who could not be withdrawn from benzodiazepines prior to ECT (Krystal et al. 1998).

ECT Administration

ECT sessions usually are scheduled for the morning. The patient's bladder should be emptied before treatment. Patients should not eat or drink for at least 6–8 hours before receiving the treatment. Famotidine or ranitidine is given the night before and the morning of ECT to neutralize the patient's gastric contents. Alternatively, sodium citrate can be given the morning of the treatment and will have an effect within 5–10 minutes. The ECT treatment team consists of a psychiatrist, an anesthesiologist (or nurse anesthetist), and a nursing team that is specially trained in ECT. The ECT treatment area should have resuscitative equipment available in case a medical emergency arises.

The historically standard anesthetic agent is methohexital, a short-acting barbiturate with minimal anticonvulsant effects. Methohexital is given in a dose of approximately 0.75–1.0 mg/kg; one alternative is propofol, given in a dose of approximately 0.75–1.50 mg/kg. Methohexital has been used more commonly because of its effectiveness and safety record. Concerns regarding the use of propofol include that it induces shorter seizures than methohexital—with propofol, some patients will not achieve a seizure lasting more than 20 seconds—and increases the number of missed seizures (i.e., delivery of an electrical stimulus without induction of a seizure) (Swaim et al. 2006). However, seizure duration has not been correlated with clinical efficacy, and trials comparing the use of

methohexital versus propofol have not shown significant differences in the antidepressive efficacy of ECT (Avramov et al. 1995) based on the anesthetic agent.

Etomidate (0.15–0.3 mg/kg) can be used instead of propofol and is associated with significantly longer seizures (Bergsholm et al. 1996; Stadtland et al. 2002) and, in one retrospective naturalistic study, was associated with a significantly shorter treatment course (Swaim et al. 2006). Another strategy that is suggested by the results of one small randomized trial is to use remifentanil, an ultrafast-acting opioid that is used to induce and maintain anesthesia, in addition to propofol. That study found that adding remifentanil had no adverse anesthetic or cardiovascular effects and patients receiving the combination anesthesia had significantly longer seizures than those receiving propofol alone (Vishne et al. 2005).

Immediately after the patient is anesthetized, a muscle relaxant is administered intravenously. Succinylcholine, at doses of 0.75–1.50 mg/kg, is a widely used depolarizing blocking agent. In patients with musculoskeletal disease, a nondepolarizing agent can be considered. Anticholinergic agents, such as atropine or glycopyrrolate, are used to prevent ECT-induced bradycardia and to minimize airway secretions. Glycopyrrolate does not cross the blood–brain barrier and therefore may be associated with less postictal confusion than atropine in the elderly. An anticholinergic agent always should be used in conjunction with a β-blocker to control the ECT-induced rise in blood pressure and heart rate. Atropine (0.4–1.0 mg) or glycopyrrolate (0.2–0.4 mg) can be given either intramuscularly 30 minutes before the ECT treatment or intravenously at the time of treatment.

The choice of electrode placement was discussed previously (see "Integrating the Science of Stimulus Dosing With the Choice of Electrode Placement"). Regardless of the electrode placement selected, meticulous care should be taken to ensure that the electrodes are properly applied. The scalp should be cleansed and prepared with a saline solution and conductive gel. The electrodes should be adequately spaced to prevent excess shunting of the electrical stimulus and to prevent skin burns. With bilateral ECT, electrodes are placed frontotemporally, with the center of each electrode approximately 1 inch (2.54 cm) above the center of an imaginary line, the endpoints of which are the tragus of the ear and the external canthus of the eye. With unilateral ECT, d'Elia electrode placement is the safest and most effective placement (R. D. Weiner and Coffey 1986). In this technique, one electrode is placed over the nondominant frontotemporal area, and the other electrode is placed high on the nondominant centroparietal scalp, just lateral to the midline vertex. The treating physician may choose to either titrate the first seizure stimulus dose or use fixed-dose ECT.

The patient is oxygenated by positive-pressure ventilation from the onset of anesthesia until spontaneous respiration is resumed. In addition, the patient is monitored with a pulse oximeter and should have his or her blood pressure and heart rate continuously monitored. Before the electrical stimulus is administered, a rubber bite block is inserted into the patient's mouth.

Regarding dosing of the electrical stimulus, the titration or *method-of-limits* approach uses a table with incremental increases in the electrical energy to determine the minimal amount of energy necessary to produce a seizure of at least 25 seconds as monitored by electroencephalography. Typically, a seizure lasting 30–90 seconds occurs during treatment. Seizures lasting longer than 3 minutes should be terminated by administering an anticonvulsant (e.g., a second dose of methohexital or a benzodiazepine). Inflating a blood pressure cuff on the right ankle before the muscle relaxant is administered allows the clinician to monitor the motor manifestations of the seizure. Patients usually are alert and oriented 20–45 minutes after receiving an ECT treatment.

If no seizure is elicited by the electrical stimulus, a detailed reevaluation should be performed. Often, immediately re-treating the patient with a higher stimulus charge is effective in producing a seizure. Medication use should be reviewed, and anticonvulsant and benzodiazepine doses should be reduced or discontinued, before subsequent ECT treatments. In situations that do not allow the reduction of

benzodiazepine doses, flumazenil, a benzodiazepine antagonist, can be used to help produce seizures.[1] Reducing the methohexital dose to the lowest effective level and using vigorous hyperventilation are other relatively easy steps that can be taken to aid in producing a seizure. Some patients who are sensitive to pain at the intravenous site (particularly when an intravenous line is inserted in a small peripheral vein) may be given intravenous lidocaine as a local anesthetic just prior to administering general anesthesia; if possible, however, lidocaine should be omitted because it can shorten the seizure length. If these methods are not effective, switching methohexital to etomidate, which should have less of an effect on the seizure threshold, may be considered (Bergsholm et al. 1996; Folk et al. 2000; Stadtland et al. 2002).

Caffeine sodium benzoate (usual dose, 120–140 mg) may be administered intravenously during ECT to maintain adequate seizure duration (Coffey et al. 1987). Caffeine appears to lengthen seizure duration during ECT without lowering the seizure threshold (McCall et al. 1993a). At present, it is not known whether caffeine augments the antidepressive effects of ECT or increases the speed of response to ECT. Theoretically, caffeine would have little therapeutic effect on unilateral ECT because the length of the seizure is less important than the degree to which the seizure stimulus exceeds the seizure threshold. Caffeine use during ECT should be reserved for patients who are having short seizures during ECT and who cannot tolerate higher stimulus doses.

Conversely, if the seizure is too long (>180 seconds), the seizure can be terminated using additional intravenous methohexital, propofol, or midazolam. Seizure length is inversely correlated with age and is particularly longer in young women. Propofol can be used as the anesthetic agent to shorten the seizure length (Bailine et al. 2003).

Frequency and Number of Treatments

The American Psychiatric Association Task Force on Electroconvulsive Therapy (2001) recommends that an ECT course be completed when a plateau in response occurs. No convincing data support that additional treatments beyond this point reduce the rate of relapse after ECT (Barton et al. 1973). In addition, the Task Force recommendations imply that rather than having clinicians predetermine the number of ECT sessions, the patient's clinical status during the course of ECT should dictate the number of treatments given.

Shapira et al. (2000) have shown that ECT administered twice weekly is as effective as treatments administered three times a week. One advantage of a more frequent treatment schedule is a faster rate of response. On the other hand, a disadvantage is the potential development of cognitive side effects. Given these observations, it is recommended that the frequency of ECT treatments be tailored to the individual patient's needs. For example, a patient with a life-threatening illness will benefit from a faster rate of response and should be given more frequent treatments. In patients for whom the risk of cognitive side effects from ECT is a particular concern (e.g., those with Alzheimer's disease, Parkinson's disease, or severe frontal lobe or caudate hyperintensities shown on a brain MRI scan, as well as those receiving outpatient or bilateral ECT), a less frequent ECT treatment schedule is certainly a reasonable choice.

[1]When flumazenil is administered to counter benzodiazepine use, it should be given immediately after seizure induction because the patient may experience sudden symptoms of benzodiazepine withdrawal. After the seizure has terminated, intravenous midazolam should be given because flumazenil has a longer half-life than methohexital and the patient may experience withdrawal on emergence from the anesthesia.

MANAGEMENT OF ECT-RELATED SIDE EFFECTS

Postictal Agitation

Postictal agitation can be a significant practical problem in ECT, with the potential for causing injury to both the patient and the nursing staff caring for the patient (Augoustides et al. 2002). Postictal agitation is difficult to predict in an individual patient but is likely to reoccur if it occurs with the initial

treatment. Postictal agitation must be differentiated from status epilepticus and is clearly distinguished by the random flailing movements of the patient in contrast to the rhythmic convulsions of a seizure and by the fact that the patient does not lose consciousness or demonstrate the fixed gaze of a patient experiencing a grand mal seizure.

Several strategies exist for treating postictal agitation, and most involve intravenous access. Midazolam or methohexital will often sedate the patient and can be very effective. Additionally, propofol can be used to manage postictal agitation (O'Reardon et al. 2006). Intravenous haloperidol has been associated with ventricular ectopy (Greene et al. 2000) and should only be used in patients with cardiac monitors. The intramuscular atypical antipsychotic medications can be just as effective, with a more benign cardiac profile.

Preventive measures can also be taken, including additional preoperative medication and changing the way ECT is administered to reduce the chance of postictal agitation in future treatments. First, the use of a dissolvable atypical antipsychotic medication such as olanzapine or risperidone 5–10 minutes prior to ECT can be very effective and does not require administration of any additional liquids. Second, current drug use should be reviewed. Lithium has been associated with postictal agitation (el-Mallakh 1988) and should be discontinued throughout the ECT course or withheld the night and morning of ECT treatments. Carbidopa has also been associated with postictal delirium and should be withheld the morning of ECT treatment (Nymeyer and Grossberg 1997). Postictal agitation may be associated with increased serum lactate levels, and some have argued that increasing the succinylcholine dose to decrease ictal muscle activity and subsequent rises in serum lactate levels can decrease postictal agitation (Auriacombe et al. 2000). Another strategy may therefore be to increase the succinylcholine dose if any muscle movement is present during the seizure. However, care should be taken because another potential cause of postictal agitation is the patient awakening from anesthesia with latent paralysis of the respiratory muscles. Patients describe this as frightening and may question continuing ECT.

The data on the effect of switching from bilateral to unilateral ECT in order to decrease postictal agitation are unclear (Augoustides et al. 2002); the success of this approach is probably dependent on several factors including ECT dosage and the patient's age.

Interictal Delirium

Interictal delirium develops during a course of ECT and persists on days when the patient does not receive a treatment. This side effect is observed primarily in elderly patients and increases in incidence with advancing age (Figiel et al. 1990). ECT-induced interictal delirium is associated with prolonged hospitalization and an increased risk of falls. Among the elderly, additional risk factors for interictal delirium are 1) Parkinson's disease, 2) Alzheimer's disease, 3) one or more cardiovascular risk factors, and 4) preexisting structural changes in the caudate nucleus observed on brain scans. Patients who develop postictal confusion are likely to have greater retrograde amnesia in the weeks and months after ECT (Sobin et al. 1995).

The incidence of delirium during a course of ECT can vary dramatically depending on the ECT technique used. As a rule, ECT-induced interictal delirium is a short-lived, reversible side effect if identified early. Once it has been identified, ECT treatments should be withheld until the delirium resolves. Subsequent treatments should be administered less frequently and/or at a lower electrical charge.

Cardiovascular Side Effects

ECT is associated with an increased risk of cardiovascular complications in elderly patients who have, or who are at risk for, cardiovascular disease. Studies have found widely varying rates of cardiac complications in the elderly receiving ECT. The retrospective design of the studies, the lack of

continuous cardiovascular monitoring, and the different definitions of what constitutes a cardiac complication probably account for the discrepancies in the results. Despite the inconsistencies, most studies have found a correlation between cardiac complications and age. ECT often produces transient systemic hypertension and abrupt transitions in cardiac rate, which can result in myocardial ischemia or arrhythmias. The increased incidence of cardiac complications among elderly patients is probably associated with the increased rate of preexisting cardiac conditions such as hypertension, coronary artery disease, and arrhythmias. On the basis of these observations, several authors have recommended the use of prophylactic cardiac medications to dampen cardiovascular responses during ECT in elderly patients who have (or are at risk for) cardiovascular disease.

Research has now documented that labetalol (a medication with both α- and β-adrenergic–blocking activity), esmolol (a shorter-acting β-blocker), and nifedipine (a calcium channel–blocking agent with vasodilating effects) can be safely used to attenuate the cardiac response during ECT (Cattan et al. 1990; Figiel et al. 1994; McCall et al. 1991; Stoudemire et al. 1990; Zielinski et al. 1993). Nicardipine (a shorter-acting calcium channel blocker) is routinely substituted for nifedipine because it can be given intravenously and has a shorter half-life.

It is recommended that adequate doses of an anticholinergic medication (intravenous atropine or glycopyrrolate) be used to prevent bradycardia whenever β-blockers are used during ECT. To help prevent ECT-induced hypotension, it is additionally recommended that all patients be adequately hydrated before undergoing ECT. If patients experience significant orthostatic hypotension in the recovery room, labetalol can be switched to the shorter-acting pure β-blocker esmolol.

The anesthetic agent propofol has been shown to have lesser cardiovascular effects than methohexital and can be used in patients with preexisting cardiac conditions requiring an attenuated hemodynamic response during treatment (Bailine et al. 2003). As noted earlier, the trade-off is a shortening of the seizure length with the use of propofol (see "ECT Administration" subsection).

Cognitive Side Effects

The greatest area of concern about ECT among the lay public, patients, and their families is the potential development of adverse cerebral and cognitive changes. The medical community's concerns about cognitive side effects and the negative images of ECT in the media also are important factors in determining the availability of ECT. The technique by which ECT is administered determines the incidence and severity of cognitive side effects that may develop during a course of ECT. Specifically, electrode placement, the type of electrical waveform, the intensity of the electrical stimulus, and the frequency of ECT sessions determine the type and severity of cognitive side effects from ECT. Preexisting structural brain changes and medical illness, advancing age, and concomitant administration of certain psychotropic medications also may be factors. It is important to recognize that depression itself (especially late-life depression) often causes cognitive deficits, such that successful treatment of depression with ECT may actually improve some aspects of cognition in certain patients. Hihn et al. (2006) showed that prefrontally mediated aspects of cognition, such as attention and immediate encoding, improved during ECT treatment of depression, whereas long-term memory functions remained impaired.

The memory loss attributed to ECT is typically anterograde and retrograde and has a temporal gradient, being more profound around the time of treatment and continuing several weeks after the ECT course (American Psychiatric Association Task Force on Electroconvulsive Therapy 2001; Sackeim 2000). The retrograde memory loss extends to months before the treatment. In most patients the anterograde memory loss clears quickly after ECT, but the retrograde memory loss can be permanent in some patients and may even extend to years before the ECT. Clearly, the degree of amnesia incurred during a course of ECT is greater with bilateral ECT than with unilateral ECT (Lisanby et al. 2000) and increases with the number of treatments administered and the stimulus intensity (Sackeim

et al. 2000). Although unilateral ECT is associated with fewer memory problems, the cognitive deficits that occur show a dose relationship and increase as the stimulus dose is increased to 8–12 times the seizure threshold (McCall et al. 2000). Research comparing bilateral and unilateral ECT has not addressed the important question of whether right-unilateral ECT given at a dose of 10–12 times the seizure threshold would cause more cognitive side effects than bilateral ECT that is minimally above or 1.5 times the seizure threshold.

Sine wave stimulus produces greater amnestic deficits than does a brief- or ultrabrief-pulse stimulus. Furthermore, Sackeim et al. (1991, 1993) reported that within a specific waveform, the magnitude by which an electrical dose exceeds the seizure threshold (rather than the absolute electrical dose) is related to the severity of cognitive defects that develop during ECT. In a prospective, naturalistic longitudinal study of cognitive outcomes in depressed patients treated with ECT at seven facilities in the New York City metropolitan area (Sackeim et al. 2007), sine wave stimulation resulted in pronounced slowing of reaction time, both immediately and 6 months following ECT. As expected, bilateral ECT resulted in more severe and persistent retrograde amnesia than right-unilateral ECT. The researchers found that several clinical variables also were associated with post-ECT memory problems, including older age, lower premorbid intellectual function, and female sex. In addition, Shapira et al. (2000) reported that twice-weekly treatments produced less cognitive impairment than did treatments administered three times a week.

The causes of the memory disturbance associated with ECT are thus multifactorial and likely include the effects of anesthetic drugs, electrode placement, stimulus waveform, generalized seizures, and electrical dose (Sackeim et al. 2007). Progress in understanding the neural mechanisms underlying memory makes it possible to consider how neurotransmitter changes might contribute to ECT-induced memory dysfunction. Muscarinic cholinergic receptors participate in some forms of memory, and antimuscarinic drugs are associated with memory impairment in humans (Krueger et al. 1992). In animals, the effects of ECS on central muscarinic systems have been variable (Fochtmann 1994). However, some studies suggest that ECS treatments diminish muscarinic binding in the cortex and hippocampus. Twenty-four hours after a series of ECS-induced seizures, decreases in levels of mRNA for M_1 and M_3 muscarinic receptors are seen in the hippocampus, although mRNA levels are significantly higher 28 days after the last seizure (Mingo et al. 1998). Other studies indicate that behavioral responses to muscarinic agonists are diminished after ECS and that brain choline acetyltransferase and acetylcholine levels are decreased (Nutt and Glue 1993). These findings suggest that alterations in muscarinic neurotransmission may contribute to memory impairment.

Long-term, use-dependent plasticity of glutamatergic synapses appears to play a major role in memory processing in the CNS, and disruption of this plasticity could contribute to anterograde amnesia. The term *long-term potentiation* (LTP) typically refers to a persistent enhancement of glutamate-mediated transmission that follows repeated high-frequency synapse use, and LTP is a potential synaptic memory mechanism. Repeated ECS treatments disrupt the induction of LTP and produce memory impairment in animals (Anwyl et al. 1987; C. Stewart and Reid 1993), suggesting a possible tie to anterograde memory problems.

Several ECS-induced changes, including effects on muscarinic and adrenergic neurotransmission, could contribute to the disruption of LTP. The enhanced inhibition that may contribute to the anticonvulsant effects of ECT could play a role because these inhibitory systems modulate efficacy at glutamatergic synapses. The release of glutamate during a seizure may also contribute to memory impairment. In many CNS regions, the induction of LTP depends on NMDA receptors. However, untimely activation of NMDA receptors before delivery of a stimulus that usually induces LTP results in LTP inhibition, a process broadly referred to as *metaplasticity.* Metaplasticity may result from activation of certain intercellular messengers, such as nitric oxide, or from the activation of phosphatases that alter the phosphorylation of key synaptic proteins (Zorumski and Izumi 1993).

Longer-term effects of ECS on basal synaptic transmission or NMDA receptor function could also contribute to memory impairment (Petrie et al. 2000). To date, there is little clinical evidence favoring any of these mechanisms in ECT-induced memory impairment, although several avenues are worth pursuing. There is some interesting evidence that verbal memory improves when an anesthetic agent that blocks NMDA receptors, ketamine, is used rather than etomidate, a GABAergic anesthetic (Krystal et al. 2003; McDaniel et al. 2006). There is also evidence that propofol, an agent that enhances GABAergic transmission but also partially inhibits NMDA receptors at anesthetic concentrations, may have beneficial effects on memory following ECT compared with thiopental (Butterfield et al. 2004).

Effects on Cerebral Physiology

Immediately after an ECT treatment, the EEG shows generalized slowing of brain wave activity. This slowing tends to increase and persist longer after successive treatments. After a course of ECT is completed, slow-wave activity gradually decreases, and EEGs show a reversion to baseline activity within 3 months (R. D. Weiner et al. 1986). Rarely, electroencephalographic abnormalities may persist for more than 3 months. Prior electroencephalographic abnormalities may increase the risk for developing prolonged abnormalities after ECT, but the clinical significance of these abnormalities is unknown.

Electrically induced seizures in animals and humans have been shown to produce transient increases in permeability of the blood–brain barrier (Laursen et al. 1991). These findings are consistent with a brain MRI study in which increased T1 relaxation times were observed after ECT (A. I. Scott et al. 1990). Laursen et al. (1991) reported that the ECT-induced increase in blood–brain barrier permeability is associated with increased stimulus intensity and an increased number of ECT treatments. In addition, Bolwig et al. (1977) were able to reduce changes in blood–brain barrier permeability during ECT by blocking ECT-induced hypertensive response with high-spinal anesthesia. Because a disturbed blood–brain barrier may predispose some patients to ECT-induced neurological complications, research is needed to examine the ways that ECT-induced changes in blood–brain barrier permeability can be minimized, such as by attenuating the ECT-induced cardiovascular response or by reducing the amount of the stimulus charge.

The combination of increased carbon dioxide production, decreased pH, and systemic hypertension that occurs with ECS treatment can cause the cerebral blood flow to increase to 300% of baseline measurements and the cerebral metabolic rate to increase by 200% (Ingvar 1986). The transient increase in cerebral blood flow results in a sharp rise in both intracranial and intraocular pressure (Maltbie et al. 1980). Both the cerebral blood flow (Saito et al. 1995) and the cerebral metabolic rate (Ackermann et al. 1986) return to baseline values during the postictal period. Methods that limit the accumulation of carbon dioxide in the bloodstream, such as forced hyperventilation, or that attenuate the increase in blood pressure tend to diminish the rise in intracranial pressure associated with ECT.

Does ECT Cause Brain Damage?

Human autopsy studies of patients who have received ECT have shown no convincing evidence of irreversible brain damage when ECT was administered with current techniques (Devanand et al. 1994; R. D. Weiner 1984). These findings are supported by a brain MRI study in which no significant structural brain changes were found immediately or 6 months after the completion of ECT (Coffey et al. 1991). In a study of six depressed patients, cerebrospinal fluid markers of neuronal/glial degeneration (τ protein, neurofilament, and S-100 β protein) were measured before and after a successful course of ECT and showed no biochemical evidence of neuronal/glial damage or blood–brain barrier dysfunction (Zachrisson et al. 2000).

Minor Complications

Patients often report nausea and headaches after ECT; these complaints usually are easily treated and

do not appear to be related to electrode placement or stimulus dose (Devanand et al. 1995). The exact incidence of nausea is not known; estimates indicate that approximately one-quarter of patients complain of some nausea (Gomez 1975). Treatments for nausea include prochlorperazine, metoclopramide, and ondansetron. If effective, they can be given prior to ECT on subsequent treatments. The anesthetic propofol can also be substituted for etomidate or methohexital to reduce post-ECT nausea and vomiting (Bailine et al. 2003).

The incidence of ECT-induced headaches is also unknown; however, some estimates are that up to 45% of patients have headaches after ECT (Devanand et al. 1995; S. J. Weiner et al. 1994). Acetaminophen or nonsteroidal anti-inflammatory agents, including intravenous ketorolac, usually are effective. The etiology of the ECT headache is unclear, but a vascular process (S. J. Weiner et al. 1994) has been suggested, and sumatriptan can also be effective (Fantz et al. 1998). Patients who have a history of migraine headaches should be given their migraine medication before ECT; prophylactic treatment with these agents immediately prior to the ECT treatment usually is effective in reducing the severity of post-ECT headaches.

PROPHYLACTIC SOMATIC TREATMENT AFTER ACUTE RESPONSE TO ECT

Although the short-term therapeutic benefits of ECT are clearly established, the 6-month relapse rate after ECT to treat depression remains high (Bourgon and Kellner 2000). The debate over appropriate prophylactic treatment for patients with an acute response to ECT has focused on the clinical decision to either continue therapy with antidepressant medications or initiate maintenance ECT. Confusion in this area persists because of the lack of controlled studies comparing the efficacy of antidepressants with that of maintenance ECT.

Most study designs have been naturalistic. O'Leary and Lee (1996) evaluated the 7-year mortality and hospital readmission rates in the Nottingham ECT cohort of patients hospitalized for major depression and found that the risk of death was double the risk in the general population, and the probability of not being readmitted was 0.79 at 16 weeks and only 0.27 over the 7-year follow-up period. Delusions were the most important clinical characteristic predicting relapse. Two studies (Aronson et al. 1987; Spiker et al. 1985) evaluated adult patients after an acute course of ECT for psychotic depression and found a combined relapse rate of 68% (n = 53) at 1 year. Spiker et al. (1985) reported a 1-year relapse rate of 50% in patients with delusional depression who initially responded to an acute course of ECT. Aronson et al. (Aronson et al. 1987) followed patients with delusional depression who had responded to either medication or ECT and found that 80% of the medication-responsive patients and 95% of the ECT-responsive patients relapsed in the first year after hospitalization. These studies did not compare the adequacy of the initial (pre-ECT) medication trial or the continuation medication trial.

In a prospective, naturalistic study of 347 depressed patients at seven hospitals, Prudic et al. (2004) found that between 30% and 47% of patients met criteria for remission at the end of their acute course of ECT. In the 24-week follow-up period, 64% of remitters relapsed. Among those patients who did not achieve remission during the acute course, only 23% had sustained remission during the 6-month follow-up period.

Sackeim et al. (1990) followed 58 patients for 1 year after ECT and found a differential relapse rate of 64% in those with major depression (with and without psychotic features) in whom an adequate pre-ECT medication trial had failed. In contrast, the relapse rate in patients who did not receive an adequate pre-ECT antidepressant trial was only 32%. Other clinical and demographic factors, including the presence of delusions, were not significant in predicting relapse. The adequacy of the post-ECT maintenance medication did not correlate with relapse rates. However, as in the studies cited above, maintenance medications post-ECT were not standardized, and evaluation of the pre-ECT medication trial was retrospective. The conclusion of this study is intuitively appealing: Patients whose symptoms do not respond to antidepressant medication before ECT are those most likely to

relapse with maintenance medication. With relapse occurring in almost two-thirds of such patients within 1 year after ECT, the relapse rate is alarmingly high.

In a prospective, randomized, double-blind trial, Sackeim et al. (2001a) compared three maintenance strategies: placebo, nortriptyline (target steady-state level, 75–125 ng/mL), and nortriptyline plus lithium (target steady-state level, 0.5–0.9 mEq/L). Over the 24-week trial, the depression relapse rate was 84% with placebo, 60% with nortriptyline, and 39% with nortriptyline plus lithium, indicating a statistically significant advantage for combination therapy. In another prospective study, Shapira et al. (1995) found that patients who responded to an acute course of ECT and subsequently received maintenance therapy with lithium for 6 months had a relapse rate of only 36%. Of the 22 patients, the 8 who relapsed did so in the first 13 weeks. Several clinical factors were associated with relapse; these included a shorter duration of the index depressive episode, an additional depressive episode in the 12 months prior to ECT, and, again, failure of an adequate trial of antidepressant therapy before the ECT course.

Lauritzen et al. (1996) randomly assigned patients with major depression who were receiving ECT to also receive either paroxetine 30 mg, imipramine 150 mg, or placebo and to continue the medication treatment after they had responded to ECT. In the continuation phase of the study, paroxetine was superior to both imipramine and placebo in preventing relapse: 65% of the placebo recipients relapsed, compared with 30% of the patients treated with imipramine and 10% of the patients treated with paroxetine.

The elderly are particularly prone to increased disability from depression and form a substantial proportion of patients in an acute ECT program. Data from naturalistic studies confirm that the relapse rates for elderly patients treated with ECT are high. These rates have varied from 21% within 6 months (Karlinsky and Shulman 1984) to 50% (10 of 20 patients) within 1 year (Murphy 1983). A naturalistic study that followed 94 patients over 3 years after an acute course of ECT noted a rehospitalization rate of 44% (Stoudemire et al. 1994). Of the 10 patients in the Murphy study who did not relapse within 1 year, 1 developed dementia and 4 died; thus, only 5 of the 20 elderly patients were well 1 year after ECT. These studies indicate that the elderly are at risk for relapse after acute ECT. However, two small studies in adolescent populations showed that younger patients also have high relapse rates: 40% within 1 year (D. Cohen et al. 1997) and 38% within 3 years (Moise and Petrides 1996).

Studies, primarily in the 1980s, have focused on finding a biological marker that would predict relapses after ECT; the possible markers included nonsuppression of cortisol in response to a challenge dose of dexamethasone (in the dexamethasone suppression test, or DST), blunted thyrotropin response to thyrotropin-releasing hormone (TRH; in the TRH stimulation test), and shortened rapid eye movement latency on a sleep EEG. These studies had many methodological flaws, including the fact that most of the studies were retrospective reviews, had nonblinded raters and a small number of subjects, and used nonstandardized follow-up treatment after ECT. Given these limitations, preliminary evidence suggests that patients who continue to show a biological marker consistent with depression after responding to ECT (e.g., a positive DST result) are at increased risk for relapse. In Bourgon and Kellner's (2000) review, six of the nine studies in which the DST was used, two of the four studies in which the TRH test was used, and the one sleep study in which shortened rapid eye movement latency was used showed that persistent abnormalities in these biological markers after ECT are predictive of relapse.

Continuation/Maintenance ECT

The high relapse rates of depression in patients receiving antidepressant medications after a successful course of ECT have led clinicians to use alternative therapies, such as continuation/maintenance ECT, in patients who are at high risk for recurrence of their mood disorder.

Continuation ECT **is defined as ECT for up to 6 months after the acute ECT course (i.e., aimed at relapse prevention). Continuation ECT is differentiated from *maintenance ECT,* which is defined as ECT that continues for more than 6 months after the initial course (i.e., aimed at recurrence prevention). In this chapter, the term *prophylactic ECT* is used to refer to any ECT treatments given as continuation or maintenance therapy. Many of the studies reviewed here do not differentiate patients receiving continuation ECT from those receiving maintenance ECT, although treatment indications, side effects, and outcomes may be different for the two types of prophylactic ECT.**

According to clinical guidelines, candidates for prophylactic ECT include patients who have recurring affective episodes that are responsive to ECT and/or who are resistant to, intolerant of, or noncompliant with antidepressant medications (American Psychiatric Association Task Force on Electroconvulsive Therapy 2001). Prophylactic ECT strategies are increasingly being used to treat major depression and bipolar disorder in patients thought to be at high risk for relapse. A 1985 survey of private psychiatric hospitals showed that 64% of the hospitals that provided ECT also provided prophylactic ECT (Levy and Albrecht 1985). Kramer (1987) found a similar pattern of use in a survey of ECT practitioners, with 59% of the 86 respondents using prophylactic ECT, primarily for recurrent depression.

Several theories have been advanced to explain the potential effectiveness of prophylactic ECT versus medication:

1. Bourne and Long (1954) suggested that patients with psychotic depression may become "convulsion dependent" such that they need to be tapered from ECT to prevent relapse.
2. Prophylactic ECT has a different mechanism of action than antidepressants, and patients with medication-resistant illness do respond to an acute course of ECT. The corollary is that patients who respond preferentially to ECT may have lower relapse rates with prophylactic ECT than with medication.
3. Prophylactic ECT may not provide a better therapeutic benefit than medication at all. Rather, the benefit may be the result of better treatment compliance in the groups receiving ECT than in those receiving maintenance medication.

Most reports of relapse rates in patients receiving prophylactic ECT include only those patients who were compliant and presented for their treatments. As Clarke et al. (1989) pointed out, when patients receiving continuation ECT do not complete 6 months of treatment, relapse rates approach the 50% rate seen in patients receiving maintenance medication. Thus, future studies of ECT need to include both compliant and noncompliant patients in their outcome measures.

A recent case study of an elderly woman with recurrent psychotic depression receiving maintenance ECT showed a correlation between resolution of cerebral hypoperfusion and a treatment response to her depressive symptoms (Suzuki 2006). At baseline, the patient demonstrated anterior cerebral hypoperfusion on single photon emission computed tomography (SPECT), which did not change 12 days after the first course of ECT. After the acute ECT course she continued to have residual depressive symptoms. Two weeks later she experienced a relapse, but her condition improved again after a second course of acute ECT. The hypoperfusion improved after the second course of ECT and resolved completely after 2 years of maintenance ECT. This case report is particularly interesting given the data by Prudic et al. (2004) demonstrating the relationship between residual depressive symptoms and relapse. Another case study, of two patients, found that cerebral blood flow and metabolic rates were no different than in control subjects prior to ECT, but that at the end of a successful continuation course of ECT, cerebral blood flow and metabolic activity in the prefrontal cortex had decreased (Conca et al. 2003), which is consistent with findings about changes in cerebral activity in response to an acute course of ECT (e.g., Nobler et al. 2001).

Most of the information on the use of prophylactic ECT has come from case reports and retrospective case series. The more recent studies have a naturalistic design with relatively few subjects, but they

generally describe a marked decrease in the number of hospitalizations, the number of days spent in the hospital, and depressive symptoms; an increase in functional status; and stable cognitive functioning for the period of continuation ECT (Clarke et al. 1989; Decina et al. 1987; Fox 2001; Gagne et al. 2000; Kramer 1999; Russell et al. 2003; Thienhaus et al. 1990; Thornton et al. 1990). These positive results extend to elderly depressed patients (Dubin et al. 1992; H. Loo et al. 1991), patients with bipolar disorder (Husain et al. 1993; Nascimento et al. 2006; Sienaert and Peuskens 2006; Tsao et al. 2004; Vanelle et al. 1994), schizophrenic patients (Shimizu et al. 2007; Suzuki 2006), and patients with Parkinson's disease (Faber and Trimble 1991; Shulman 2003). A moderately sized study of treatment-resistant schizophrenia patients who were responsive to acute treatment with a combination of ECT plus antipsychotic medication found that these individuals fared better with the combination of continuation ECT plus the antipsychotic medication than with either treatment alone (Chanpattana et al. 1999a).

In a prospective study, Clarke et al. (1989) used continuation ECT in 27 patients who received an acute course of ECT to treat major depression because of a history of medication intolerance or resistance. The rate of rehospitalization was six times lower (8%) in patients who completed a 5-month course of continuation ECT than in patients who did not complete the protocol (47%). Swoboda et al. (2001) prospectively followed 13 patients diagnosed with major depression and 8 patients who had schizoaffective disorder who were administered maintenance ECT and compared them with controls who received maintenance pharmacotherapy alone. The maintenance ECT group had a significantly lower rate of rehospitalization at 1 year than control subjects, although the schizoaffective patients had a poorer outcome overall than patients with major depression. The largest prospective study of continuation ECT to date included 184 patients who were randomly assigned to receive either maintenance pharmacotherapy with a combination of lithium and nortriptyline or continuation ECT for 6 months; both treatments had limited efficacy, with more than half of patients in each group either relapsing or dropping out of the study (Kellner et al. 2006). Although these results were disappointing, the efficacy of continuation ECT was being compared with that of the "gold standard" of nortriptyline and lithium, and both treatments were superior to placebo (using historical placebo controls) or follow-up with monotherapy. There are few other prospective studies and/or controlled trials of continuation or maintenance ECT.

Studies that have evaluated the side effects of maintenance ECT on memory are limited. A retrospective study of 18 patients receiving maintenance ECT for 3–10 months showed minimal memory side effects and an excellent clinical response (Abraham et al. 2006). Three patients (17%) had slightly impaired memory, which improved to normal, and one patient experienced severe memory problems in the third month and discontinued treatment. Another study found no difference in the neuropsychological functioning of 13 patients receiving maintenance pharmacotherapy and 11 patients receiving maintenance ECT after an acute course of ECT (Vothknecht et al. 2003). A telephone screening system for evaluating cognitive side effects of maintenance ECT has been proposed that successfully identified a patient with significant deficits the day after an ECT treatment (Datto et al. 2001). This type of monitoring would be practical for evaluating patients receiving maintenance ECT in both clinical and research settings.

Guidelines for the use of prophylactic ECT unfortunately remain vague, primarily because of the paucity of data on which to base guidelines. Monroe (1991) delineated the contradiction of the increasing use of prophylactic ECT and the lack of research defining the parameters of administering the treatments and their potential side effects and contraindications. More recently, the National Institute for Clinical Excellence (NICE) Technology Appraisal, "Guidance on the Use of Electroconvulsive Therapy," questioned the use of continuation and maintenance ECT because of the lack of empirical evidence. From their examination of the data, the authors concluded that ECT is "not recommended as a maintenance therapy in depressive illness" (NICE 2003). Other researchers have challenged this conclusion, pointing out that the typical patient receiving continuation or maintenance

ECT has chronic relapsing depression that has failed to respond to multiple medication trials (Frederikse et al. 2006). In fairness, it should be pointed out that the NICE report was published before the above-cited studies by Prudic et al. (2004) and Kellner et al. (2006), two prospective studies supporting the use of continuation ECT.

Patients Who May Benefit From Prophylactic ECT

Patients who receive prophylactic ECT after an acute course of ECT usually fall into one of three categories:

1. Patients whose illness has failed to respond to previous trials of medications and are therefore relatively medication resistant
2. Patients who are severely ill (e.g., psychotic or suicidal)
3. Patients who cannot tolerate the side effects of antidepressant medications, because of either concomitant medical illness or a personal sensitivity to antidepressants' side effects, or who are noncompliant with their medication

These groups overlap and include patients who, because of their own experience or the experiences of acquaintances or relatives, prefer ECT to the traditional somatic treatments.

Patients Who Have Failed to Respond to Previous Trials of Medication

A significant minority of patients with major depression are relatively medication resistant despite adequate medication trials (trials of antidepressants with adequate doses and length of treatment to elicit a response). Sackeim et al. (1990) noted that the most important factor in relapse after an acute course of ECT that enables a patient to achieve remission is whether the patient participated in an adequate medication trial prior to ECT. The relapse rate in the 6 months following ECT was found to be twofold higher in patients who had participated in an adequate medication trial than in those who had not (Sackeim et al. 1990). Shapira et al. (1995) also found that patients who had received adequate previous treatment with pharmacotherapy relapsed post-ECT (while receiving lithium maintenance therapy) at a significantly higher rate than did patients who had not received adequate prior medication. Interestingly, Grunhaus et al. (1990) reported a relapse rate of only 17% in patients in whom a previous medication trial had failed and who received up to 12 weeks of prophylactic ECT after a successful initial course of ECT.

Patients in whom an adequate medication trial failed before ECT was initiated should be informed of the risk of relapse and given the option of receiving continuation ECT for 6 months, followed by maintenance medication. The clinical decision of whether to continue ECT beyond 6 months should be made on an individual basis, weighing the risks (primarily the cognitive effects of ongoing ECT vs. the risk of suicide or recurrent psychosis if the patient relapses while taking medication) and benefits (the long-term effects of a period of mood stability).

Patients Who Are Severely Ill

Some researchers have found that the 1-year relapse rate in patients with psychotic depression treated with medication alone may be as high as 95% (Aronson et al. 1987; Spiker et al. 1985). Petrides et al. (1994) retrospectively examined the records of patients with delusional depression treated with prophylactic ECT and found the relapse rate at 1 year to be only 42%. They compared their findings with those from the study by Aronson et al. (1987). Both patient groups were drawn from the same institution, although prophylactic ECT was not available at the time that Aronson et al. (1987) reported relapse rates of 95% in patients with delusional depression who were taking antidepressants. Vanelle et al. (1994) prospectively administered maintenance ECT, often with concomitant antipsychotic medication, approximately once a month for 1 year to a group of patients with psychotic depression and found full or partial remission in 80% of the patients. Grunhaus et al.

(1990) also found an excellent clinical response in patients with psychotic depression who were administered prophylactic ECT. Prophylactic ECT may therefore be a viable option in patients with delusional depression and should be discussed with these patients and their families.

Patients Who Cannot Tolerate the Side Effects of Antidepressant Medications or Who Are Noncompliant With Their Medication

Most patients who cannot tolerate the side effects of antidepressant medications because of either concomitant medical illness or a personal sensitivity to antidepressants' side effects can benefit from trying maintenance medication after a successful course of ECT. Many patients who are acutely ill may be extremely sensitive to the side effects of medications but may tolerate the same medication once they have responded to acute treatment with ECT. Conditions associated with depression, such as malnutrition and dehydration, may worsen the orthostatic hypotension caused by tricyclic antidepressants. In a patient with agitated depression, minimal activation from the SSRIs may be experienced as extreme agitation. Once the depressive episode has remitted, patients usually can tolerate an additional trial of medication. Patients who are noncompliant with their antidepressant medication should be evaluated on an individual basis and, after discussions with the patient and the family, the risks and benefits of prophylactic ECT should be weighed against those of an additional medication trial.

Guidelines for Prophylactic ECT

Treatment Parameters

The electrode placement and dose parameters used in the initial course of ECT are maintained during continuation and maintenance ECT. Retrospective reviews have not found that stimulus placement affects the clinical outcome (Petrides et al. 1994), although no systematic studies have compared unilateral and bilateral placement in prophylactic ECT. Since seizure threshold can increase during acute treatment because of the frequency of treatments, the threshold would be expected to decrease during prophylactic ECT. In one small study the threshold was shown to decrease significantly when the treatments were separated by 60 days or more (Wild et al. 2004).

Few guidelines exist on what frequency of prophylactic ECT is optimal to maintain mood stability. The intervals between courses of continuation ECT in the studies reviewed vary from 3–5 weeks (H. Loo et al. 1991) to 4–8 weeks (Thienhaus et al. 1990). Other clinicians argue that treatments should be gradually tapered from once a week to once a month, depending on clinical response (Aronson et al. 1987; Clarke et al. 1989; Matzen et al. 1988). Kramer (1987) surveyed 51 clinicians in 24 states and found the frequency and duration of maintenance ECT to vary from as often as two treatments per week to once every 3–4 weeks for 30 months to one treatment every 6 months for 60 months to as long as 48 years. In Kramer's survey, clinicians described continuing ECT until the patient was asymptomatic for a predetermined period ranging from 1 month to 2 years.

Grunhaus et al. (1990) assessed individual patients' clinical histories and assigned them to receive either abbreviated continuation ECT (once or twice a week for 4–12 weeks) or full continuation ECT (gradually tapering ECT frequency to once a month over 3 months and continuing ECT once a month for 6 months). Abbreviated continuation ECT was used when symptoms were unresponsive to medication after the index depressive episode and lasted more than 12 months, or when the patient relapsed after a successful course of ECT or had difficulties tolerating continuation pharmacotherapy. Full continuation ECT was used in patients who relapsed after a successful course of ECT despite adequate pharmacotherapy. Among 10 patients, these researchers found an excellent response in 6 (5 of 6 patients receiving abbreviated continuation therapy; 1 of 4 patients receiving full continuation therapy), particularly in those with delusional depression.

In their prospective study, Vanelle et al. (1994) administered maintenance ECT with an average

frequency of once every 3.5–3.9 weeks for 1 year and found that 64% of the patients (*n* = 22) needed shorter intervals between treatments to prevent a recurrence of their depressive disorders. The patients who required a shorter interval were older and had a longer duration of illness. Vanelle et al. (1994) posited that the older patients may have had a shorter time to relapse, a suggestion that is consistent with data showing that older patients tend to have accelerated mood cycles (Zis et al. 1980). Others have suggested tapering the ECT treatments from once a week for 4 weeks to once every 2 weeks for 4 weeks and then to once monthly for 4–6 months (Fox 2001).

Treatment Considerations

The greatest risk of relapse after ECT is within the first few months after acute treatment (Clarke et al. 1989; Sackeim et al. 1990; Shapira et al. 1995). During this crucial period, many patients and their families describe a recurrence of symptoms of depression when prophylactic ECT treatment intervals are extended by even a few days. This pattern of response has resulted in the development of a continuation ECT protocol in which treatment intervals are extended in increments—from once a week for the first four treatments to every 10 days for the next three treatments and then to every 2 weeks for the final 4 months. During the initial 6 months of prophylactic ECT, treatments are not extended beyond every 2 weeks. If a patient becomes symptomatic, the treatment interval is again shortened until the patient is clinically stable. Usually this requires an additional 3–4 treatments and not a full acute course of 6–10 treatments. The patient then resumes the longest ECT treatment interval during which he or she remained healthy.

Patients are encouraged to continue ECT for at least 6 months. In the final month of continuation ECT, treatment with an antidepressant is initiated. However, which antidepressant drugs can be safely and effectively used during continuation ECT requires further study. For patients who relapse quickly after continuation ECT ends, maintenance ECT should be considered.

Informed Consent

Individual hospital policies and state laws dictate the procedure for obtaining informed consent. The administration of prophylactic ECT on an outpatient basis is subject to the same guidelines that apply to the ambulatory surgery service in the treating hospital. In general, the same policies governing consent for the initial ECT course apply to the prophylactic course of ECT. The consent procedures have been reviewed extensively elsewhere (Abrams 1997; American Psychiatric Association Task Force on Electroconvulsive Therapy 2001). A new consent should be obtained before each course of prophylactic ECT, when a patient changes from inpatient to outpatient status, and at least every 6 months. The physician also should document at the beginning of each ECT course (i.e., at the time of the consent) the justification for the prophylactic ECT.

Cognitive Complications

Few data exist on the cognitive changes that patients experience while receiving repeated ECT treatments over a period of months to years. Most of the available reports in which prophylactic ECT has been used describe only minor subjective complaints (e.g., Fox 2001). Grunhaus et al. (1990) reported that the patients in their study experienced minor memory difficulties (recent recall and names) that resolved within 6–8 months. Patients in the study by Vanelle et al. (1994) (mean age, 70 ± 13 years) described either no subjective memory problems (*n* = 8) or minor subjective cognitive complaints (*n* = 14). Petrides et al. (1994) noted only minor subjective memory problems in 30 patients (mean age, 52 ± 15 years) who received an average of seven continuation ECT treatments over 2 months. Thienhaus et al. (1990) found stable cognitive function (as measured on the Mini-Mental State Exam) in six elderly patients (mean age, 71 ± 5 years) receiving prophylactic ECT for 1–5 years. A naturalistic 1-year study of 20 persons receiving maintenance ECT found no global cognitive decline over the course of the study (Rami et al. 2004).

TRANSCRANIAL MAGNETIC STIMULATION AND SUBCONVULSIVE STIMULI

To date, there are a number of subconvulsive treatments for depression including TMS, vagus nerve stimulation (VNS), and deep brain stimulation, all of which hold promise both for the treatment of depression and for elucidating the underlying biology of depression.

These treatments bring into question the axiom that subconvulsive stimuli cannot be therapeutic. Prototypes of the modern subconvulsive brain stimulation devices were first developed by Pollacsek and Beer in 1903. These colleagues of Sigmund Freud used electromagnetic currents to stimulate cortical neurons, but it was not until 80 years later that Barker developed modern TMS equipment (Barker et al. 1985) and research began to focus on the effects of TMS on psychiatric disorders. TMS equipment is relatively simple and uses capacitors to store an electrical charge. The charge is then discharged through a coil and produces a magnetic field that lasts from 100 to 200 milliseconds. When placed over the skull, the magnetic field passes unimpeded into the brain, stimulating the underlying brain regions; TMS can be used to assess both motor function (Homberg et al. 1991) and other complex brain functions such as speech (Epstein et al. 1996) and visual information processing (Beckers and Zeki 1995). Early preclinical studies of TMS in rats showed that TMS had effects similar to those of ECS in behavioral models of depression, including enhancement of apomorphine-induced stereotypy, reduction of immobility in the Porsolt swim test, and increases in seizure threshold on subsequent stimulation (Fleischmann et al. 1995; Lisanby and Belmaker 2000).

Rapid-Rate Transcranial Magnetic Stimulation

Within a decade of the development of modern TMS equipment, TMS was being used to treat depression and schizophrenia (Grisaru et al. 1994; Hoflich et al. 1993; Kolbinger et al. 1995). These studies used TMS coils that were nonfocal, and the antidepressive effects were limited. Additional work by George et al. (1995) provided the impetus for a renewal in TMS research in mood disorders. These studies used rTMS—repetitive or rapid-rate TMS—to apply multiple stimuli in one session and target treatment to the prefrontal cortex, an area that has been shown to be important in the response to ECT (Nobler et al. 2001). Imaging studies have demonstrated a response to rTMS based on changing metabolic patterns in the frontal cortex (Kimbrell et al. 1999). Yet the magnitude of the response to rTMS is rarely more than a 50% decline in the depression rating scales (e.g., clinical criteria for response), and few patients meet the criteria for clinical remission (or an absolute value for a scale that indicates no evidence of depression). A meta-analysis noted that although rTMS was clearly superior to sham stimulation and the effect size was moderate (effect size = 0.81 [95% confidence interval = 0.42–1.20; $P < 0.001$]), the clinical significance was modest (Holtzheimer et al. 2001).

Studies comparing rTMS and ECT have shown that the efficacy of rTMS is equivalent to that of ECT for the treatment of major depression (Grunhaus et al. 2000; Janicak et al. 2002). A combination of ECT and rTMS has been shown to be as efficacious as ECT alone (Pridmore 2000) and could potentially produce fewer side effects. Some researchers have pointed out that studies comparing ECT and rTMS have had unusually low response rates in the ECT treatment arms, suggesting possible underdosing of ECT (Euba 2005; Kellner et al. 2002; Schulze-Rauschenbach et al. 2005). A recent study found rTMS less efficacious than "a standard ECT course" for relieving acute symptoms of depression, without appreciable differences in cognitive side effects (Eranti et al. 2007).

Recent data from an industry-sponsored trial demonstrated a modest effect for rTMS in the treatment of depression. In this study, 301 medication-free patients participated in a double-blind multisite study using sham stimulation in control subjects (O'Reardon et al. 2007). The response rate at week 4 was significant, indicating a 50% decline in depression scores for approximately 18% of patients in the active treatment group versus 11% of those in the sham control group (and 24% vs. 12% at week 6). The remission rates at week 6, but not at week 4, were also significant (14% vs. 5%). In October

2008, the U.S. Food and Drug Administration (FDA) approved the use of rTMS for treatment of patients with depression who have failed to respond to an antidepressant treatment trial.

rTMS clearly has several advantages over ECT. rTMS requires no anesthesia, is easy to administer, and has only transient, mild cognitive side effects. Furthermore, rTMS does not have the negative stigma associated with ECT. Yet some physicians question whether the subconvulsive stimuli of rTMS can have an antidepressive effect comparable to that of ECT (Swartz 1997). A technique called *magnetic seizure therapy* has been developed as another alternative to ECT, combining the therapeutic effect of a seizure with the more focused stimulation of rTMS (Lisanby et al. 2001b, 2001c). Magnetic seizure therapy initiates a tonic–clonic seizure using a magnetic stimulator that focuses on a specific area of the brain and delivers a peak electrical charge that is comparable to that of an ECT treatment. The potential advantage of magnetic seizure therapy is that the maximum voltage can be focused on an area associated with a therapeutic benefit (e.g., the prefrontal cortex) and spare areas associated with debilitating side effects (e.g., the hippocampus). Magnetic seizure therapy offers the opportunity to target areas for stimulation and has some advantages over ECT, which affects multiple cortical and subcortical areas. Work in this area is ongoing and still in the preliminary stages.

Vagus Nerve Stimulation

Approved by the FDA for use in patients with treatment-resistant epilepsy, VNS therapy exerts its effect by applying intermittent subconvulsive electrical stimulation to the left vagus nerve. The left vagus nerve has autonomic connections to limbic and cortical areas known to be involved in mood regulation (George et al. 2000; Nemeroff et al. 2006), and as previously discussed, a putative effect of ECT is to act as an anticonvulsant (Sackeim 1999) (see "Anticonvulsant Hypothesis" subsection). Studies of the effect of VNS on mood regulation in a small sample of patients with epilepsy demonstrated a trend toward mood improvements (Elger et al. 2000) or showed a positive effect on mood that was no different from that seen in a group of epilepsy patients treated with anticonvulsant medications alone (Harden et al. 1999, 2000). However, a 10-week open pilot study of 60 depressed nonepileptic patients showed a response rate of 31% and a remission rate of 15% (Rush et al. 2000; Sackeim et al. 2001c), and the initial treatment response continued over the following 2 years (Nahas et al. 2005).

These pilot data served as the basis for a larger multicenter trial with 222 patients (Rush et al. 2005a). The study design included a 2-week single-blind recovery period after implantation (during which patients received no stimulation), followed by 10 weeks of masked active VNS treatment or sham treatment. At 10 weeks, response rates were 15% for the active treatment group (n = 112) and 10% for the sham treatment group (n = 110) (P = 0.251). Although this study did not yield definitive evidence of short-term efficacy for adjunctive VNS in patients with treatment-resistant depression, the subjects were then followed for a year in a naturalistic study in which they had stimulator adjustments and could have their medication changed or receive other treatments for depression (Rush et al. 2005b). These caveats should be kept in mind when considering that the 1-year response rate was 27% (55/202) and the remission rate was 16% (32/202). The patients showed significant improvement when compared with a matched control group of patients with similar treatment-resistant depression who were receiving only medication (George et al. 2005). The FDA considered these data and approved VNS therapy for treatment-resistant depression, although it required the patients receiving VNS to be followed to determine the long-term treatment response.

Comparison With ECT

Although rTMS and VNS provide therapeutic alternatives for patients with depression, neither provides the efficacy of ECT. The response to ECT is remarkable given the data that more than 80% of depressed patients may achieve remission despite multiple medication failures. However, ECT is expensive, has been stigmatized, and has significant side effects, including long-term memory loss.

Furthermore, after responding to an initial course of ECT, patients face a relapse rate of up to 60% within 6 months while receiving antidepressant medication. Prophylactic ECT to prevent relapse and remission is a viable and cost-effective option (McDonald et al. 1998) but can be difficult to implement, given the time demands and potential side effects. Time constraints may also hinder the use of rTMS, which, although it requires no anesthesia, is easy to administer, and has only transient, mild cognitive side effects, can be impractical because the patient is required to come in 5 days a week for up to 6 weeks. Disadvantages of VNS are that it is expensive and requires surgery and adjustments of the stimulator.

Like ECT, pharmacotherapy, and psychotherapy, both rTMS and VNS are relatively nonspecific: the treatment effects target areas of the brain and circuits involved in depression, rather than specific nuclei and nodes. This lack of specificity may be an advantage in that major depression is a relatively nonspecific disease that includes diagnoses as disparate as postpartum depression and depression secondary to stroke. The lack of specificity may also account for the suboptimal response to treatment with antidepressant drugs in patients with major depression. (This point was recently highlighted by the Sequenced Treatment Alternatives to Relieve Depression [STAR*D] trial, which found a 37% remission rate in patients treated with a selective serotonin reuptake inhibitor [Rush et al. 2006].)

Deep Brain Stimulation

Deep brain stimulation is the most highly focused treatment for depression—it is the treatment that most specifically targets the neural networks involved in depression—and has shown promise as a subconvulsive stimulus. It has been used in treatment-refractory Parkinson's disease and was the direct result of preclinical research that outlined the neural circuits and underlying positive and

and as a prophylactic treatment for depression has been shown to be both effective and cost-efficient compared with medication. Alternative strategies such as rTMS have recently attracted increasing interest as possible replacements for ECT, but these treatments are clearly still in the investigational phase. For patients with severe, treatment-resistant depression, ECT remains the gold standard.

Chapter 45. Neurobiology of Mood Disorders

INTRODUCTION AND HISTORICAL CONTEXT

The search for the biological substrates of affective disorders spans many centuries. Indeed, Hippocrates (460–357 B.C.) speculated that melancholia emerged when environmental conditions, such as the alignment of the planets, caused the spleen to secrete black bile, which then darkened the mood. During the next 2,000 years, few significant contributions to our understanding of mood disorders emerged until Robert Burton's *Anatomy of Melancholy* (1621). Positing that depressed people often "are born of melancholy parents," Burton anticipated the genetic underpinnings of melancholia as well as other factors in the pathogenesis of depression, including alcohol, diet, and biological rhythms. Through his careful longitudinal observations, Emil Kraepelin (1856–1926) was subsequently able to detect a genetic contribution to manic-depressive illness. Kraepelin also hypothesized that other constitutional factors resulted in specific brain abnormalities in manic-depressive patients, although postmortem tissue studies were unrevealing.

Adolf Meyer (1866–1950), at Johns Hopkins University, attempted to integrate psychological and biological theories of mental illness. Coining the term *psychobiology,* he speculated that depression was the result of genetic or biological factors, with additional effects of the environment after birth. Influenced by the work of Freud and other contemporaries, Meyer also emphasized the importance of current life stressors in the generation of depressive symptoms.

Investigation into the pathophysiological basis of psychiatric illness retreated with the preeminence of psychoanalytic theory and practice during the immediate post–World War II era. Biological theories reemerged in the 1950s after the introduction of the effective antipsychotic agent chlorpromazine and were further fostered by the introduction of effective antidepressants. Furthermore, the biogenic amine hypothesis (attributed to Joseph Schildkraut, John Davis, and William Bunney, with additional contributions by Alec Coppen and I. P. Lapin) posited that major depression was caused by a deficiency in central nervous system (CNS) concentration or receptor function of the neurotransmitters norepinephrine (NE), epinephrine, and dopamine (DA) or the indoleamine serotonin (5-hydroxytryptamine [5-HT]).

American investigators during the 1960s, including Schildkraut (1965) and Bunney and Davis (1965), developed a variation of the biogenic amine hypothesis—the catecholamine hypothesis. The catecholamine hypothesis of affective disorders proposes that some types of depression are associated with a relative deficiency of catecholamines, particularly NE, in the CNS, whereas mania is associated with a relative overabundance of catecholamines. Substantial data have accumulated, however, documenting the contributions of other putative neurotransmitters in the maintenance of mood.

As American investigators during the 1960s focused on the importance of NE in the pathogenesis of abnormal mood states, European researchers—Alec Coppen (1968) in England and Lapin and Oxenkrug (1969) in the Soviet Union—turned their attention to the CNS serotonergic system. They proposed that a deficiency in serotonergic neuronal function produced depressive symptoms. This hypothesis was bolstered by the observations of Åsberg et al. (1976b) that a sizable subgroup of

depressed patients had low cerebrospinal fluid (CSF) concentrations of 5-hydroxyindoleacetic acid (5-HIAA) and moreover that this subgroup was at greater risk for attempting or committing suicide, particularly by violent means. The association between indices of reduced 5-HT turnover and impulsive violent behavior was consistently replicated in several studies (Roy et al. 1989; Träskman et al. 1981; Van Praag 1982), although it does not appear to be specific to depression (V. M. Linnoila and Virkkunen 1992; Virkkunen et al. 1994).

In the 1970s, Janowsky et al. (1972) proposed a variation in the catecholamine hypothesis: they suggested that a relative increase or decrease in CNS cholinergic activity is associated with depression or mania, respectively.

Concurrent with the aforementioned work, psychiatrists repeatedly observed disturbances in mood in patients with clinical endocrinopathies. Indeed, hypercortisolemia was first noted as a feature of major depression in the late 1950s. During the 1970s, great strides were made in the understanding of the neuroendocrine mechanisms underlying major depression, including perturbations of the hypothalamic-pituitary-adrenal (HPA) and the hypothalamic-pituitary-thyroid (HPT) axes. Carroll's group demonstrated that 40%–50% of patients with endogenous depression show resistance to dexamethasone-induced HPA axis suppression, in the now well-known dexamethasone suppression test (DST) (W. A. Brown et al. 1979; Carroll et al. 1968b). Prange and colleagues detected abnormalities in the HPT axis in patients with major depression (Prange et al. 1972) and also reported that augmentation of antidepressant treatment with the thyroid hormone triiodothyronine (T_3) was effective (Prange et al. 1969).

The biogenic amine hypotheses also arose in part from pharmacological interventions and observation of their effects on mood. Reserpine, a rauwolfia alkaloid antihypertensive agent, produces depressive symptoms in many patients, presumably resulting from depletion of biogenic amines from CNS neurons. The mood-elevating action of monoamine oxidase inhibitors (MAOIs) was discovered by the chance observation of the effects of iproniazid, a drug originally developed to treat tuberculosis. Imipramine, a tricyclic compound related to chlorpromazine and originally designed to treat schizophrenia, was demonstrated to be an effective antidepressant. Tricyclic antidepressants (TCAs) not only block the reuptake of NE and 5-HT into presynaptic neurons but also are muscarinic cholinergic receptor antagonists. Shopsin et al. (1975, 1976) found that administration of p-chlorophenylalanine, an inhibitor of 5-HT synthesis, reversed the antidepressant action of imipramine, as well as tranylcypromine, an MAOI. Interest in the mechanistic role of serotonergic systems in depression was further stimulated by the introduction of selective serotonin reuptake inhibitors (SSRIs) (e.g., fluoxetine) in the late 1980s. During the 1990s and the initial part of the present century, advances in molecular biology have made possible the structural characterization and cloning of several 5-HT receptors, as well as of the serotonin transporter (5-HTT).

More recently, research examining the role of developmental stress, trauma, and gene–environment interactions in the etiology of particular subtypes of depression and other forms of psychopathology (Caspi et al. 2003; Chapman et al. 2004; Dube et al. 2001; Heim et al. 2000; Kaufman et al. 2006; Kendler et al. 2001b; McCauley et al. 1997) and medical illness (Batten et al. 2004; Caspi et al. 2006; Danese et al. 2007; Dong et al. 2004; Felitti et al. 1998; R. D. Goodwin and Davidson 2005; R. D. Goodwin and Stein 2004; Lissau and Sorensen 1994; G. D. Smith et al. 1998) has had a large impact on mood disorders research and is clearly a burgeoning area for understanding relationships between environmental and genetic risks with respect to medical and psychiatric comorbidity.

Clinically, mood disorders are syndromal illnesses characterized by symptomatology suggestive of the disruption of a variety of brain regions/neural systems within the CNS. These include the frontal cortex, cingulate, hippocampus, striatum, amygdala, and hypothalamus that together participate in the regulation of mood, sleep, motivation, energy balance, and cognition (Nestler et al. 2002). This view is supported by a very large body of multidisciplinary research using state-of-the-art genetics

and molecular neurobiology, biomarkers, responses to physiological challenge tests, structural and functional imaging, psychological testing, and postmortem studies. These data, however, suggest that mood disorders are not likely to be diseases resulting solely from dysfunction of a single gene, brain region, or neurotransmitter system. Rather, mood disorders likely represent distinct disorders with overlapping phenomenology and pathophysiology. Subtypes of depression likely differ with respect to allelic patterns of genetic vulnerability (or resilience), changes in gene regulation, and abnormal signaling at the cellular and systems levels within the CNS and between the CNS and other organ systems of the body—in short, they are systemic diseases (Belmaker and Agam 2008; Manji et al. 2001; Mayberg 1997; Nemeroff 2002; Nestler et al. 2002). In this chapter, we provide an overview of research examining the neuroendocrinology, neurochemistry, neuroimmunology, genetics, and brain imaging alterations of patients with mood disorders.

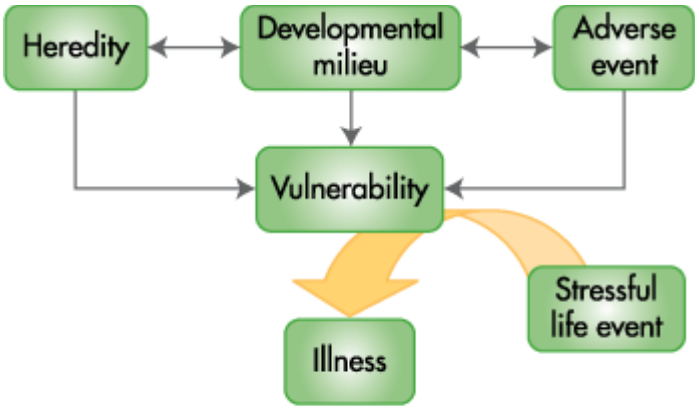
EPIDEMIOLOGY

Over the past 30 years, epidemiological studies of the major mood disorders have reported considerable variation in the prevalence rates of depression and bipolar mood disorder. This variability may be explained by the differing methodology of these surveys: the sampling of the populations at risk, the particular diagnostic system used, the method for obtaining information about symptoms, and the time when information was obtained (Weissman et al. 1992).

Most recently, the National Comorbidity Survey Replication (NCSR) reported the following 12-month prevalence rates of mood disorders based on DSM-IV-TR (American Psychiatric Association 2000) criteria: major depression (6.7%), dysthymia (1.5%), and bipolar I and II disorder (2.6%) (Kessler et al. 2005). Of the mood disorders, major depressive disorder is the most common psychiatric disorder (Kessler et al. 2003). In the United States, the lifetime prevalence of depression is nearly 17% (Kessler et al. 2005). Worldwide, depression remains a leading cause of disability (Murray and Lopez 1996; WHO World Mental Health Survey Consortium 2004).

THE NEUROENDOCRINE AXES



Several psychiatric disorders, including the major mood disorders, are associated with specific highly reproducible neuroendocrine alterations. Conversely, certain endocrine disorders (e.g., hypothyroidism and Cushing's disease) are associated with higher-than-expected rates of psychiatric morbidity. Neuroendocrine abnormalities have long been thought to provide a unique "window to the brain," revealing clues about the pathophysiology of specific CNS neurotransmitter systems in the particular psychiatric disorder under study. This so-called neuroendocrine window strategy is based on an extensive literature that indicates that the secretion of the peripheral endocrine organs is largely controlled by their respective pituitary trophic hormone. This pituitary hormone secretion, in turn, is controlled primarily by the secretion of the hypothalamic release and release-inhibiting hormones. Unipolar depression (and to a lesser extent bipolar disorder) is associated with multiple endocrine alterations, specifically of the hypothalamic-pituitary-adrenal/thyroid/growth hormone axes. In addition, a continually growing body of evidence indicates that components of the neuroendocrine axes, such as corticotropin-releasing hormone (CRH), may themselves directly contribute to mood symptomatology.

Hypothalamic-Pituitary-Adrenal Axis

Excess secretion of cortisol (Carpenter and Bunney 1971; Gibbons and McHugh 1962) and its metabolites (Sachar et al. 1970) was first observed in depressed patients more than 40 years ago. Moreover, the prominent presence of depression and anxiety in patients with endocrinopathies affecting the HPA axis such as Cushing's disease or syndrome (Dorn et al. 1995, 1997) in conjunction with the observation of increased secretion of cortisol in healthy patients exposed to stress

contributed in part to the development of the stress–diathesis model of depression (Figure 45–1). This model hypothesizes that individual predisposition to excess reactivity of the neural and endocrine stress response systems plays a seminal role in susceptibility to depression. The presence of acute or prolonged stress in vulnerable individuals is thus believed to play a significant role in both the onset and relapse of certain forms of depression and may also contribute to the burden of medical illness in patients with depression (E. S. Brown et al. 2004). A wide variety of abnormalities of HPA axis function have been identified in patients with unipolar depression and bipolar disorder and are described below.

FIGURE 45–1. Stress–diathesis model of depression.

Functional Organization of the HPA Axis

The discovery of CRH (Vale et al. 1981) greatly accelerated research into the biology of stress and helped clarify the organization of the HPA axis, a collection of neural and endocrine structures that function collectively to facilitate the adaptive response to stress. Parvocellular neurons of the paraventricular nucleus (PVN) of the hypothalamus project to the median eminence where they secrete CRH into the primary plexus of blood vessels that comprise the hypothalamo-hypophyseal portal system (Swanson et al. 1983). The secreted CRH is then transported to the anterior pituitary gland, where it activates CRH_1 receptors on pituitary corticotrophs, resulting in increased secretion of adrenocorticotrophic hormone (ACTH). ACTH released from the anterior pituitary into the systemic circulation subsequently stimulates the production and release of cortisol from the adrenal cortex by activation of type 2 melanocortin receptors. Two glucocorticoid-responsive receptors, the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR), have been identified within the brain (Joels and de Kloet 1994). MRs have a high affinity for glucocorticoids and are restricted within the brain to limbic structures such as the septum, hippocampus, and amygdala where they regulate basal activity of the HPA axis (Jacobson and Sapolsky 1991). In contrast, GRs have a lower affinity for glucocorticoids than MRs and are distributed throughout the brain but are densely concentrated within the limbic system, parvocellular division of the PVN, pituitary, and ascending monoaminergic projection neurons. With elevated activity of the HPA axis, circulating levels of cortisol increase and the lower-affinity GRs become occupied, leading to suppression of HPA axis activity through effects at the hippocampus, PVN, and pituitary (de Kloet et al. 1991). Mechanistically, these effects appear to be nongenomic and may act by triggering secretion of endocannabinoids from CRH-containing cells of the PVN. Endocannabinoids released from the PVN act through type 1 cannabinoid receptors to dampen the activity of glutamatergic afferents to the PVN, which subsequently reduces the neural outflow of the PVN (Di et al. 2003). Feedback inhibition, mediated in part by activity of MRs and GRs at multiple anatomical sites within the CNS, thus reduces stress-induced activation of the HPA axis and limits

excess secretion of glucocorticoids, effectively dampening the stress response (Jacobson and Sapolsky 1991).

In addition to its major role in the regulation of the HPA axis, CRH is widely distributed in areas of the brain outside the hypothalamus, including the amygdala, septum, bed nucleus of the stria terminalis, and cerebral cortex (Swanson et al. 1983), where it functions, along with the hypothalamic CRH system, as a neurotransmitter in coordinating the behavioral, autonomic, endocrine, and immune responses to stress (Arborelius et al. 1999). Two CRH receptor subtypes (CRH_1 and CRH_2), both coupled positively to the production of adenylate cyclase (Chalmers et al. 1996), appear to mediate divergent effects of CRH on behavior (Heinrichs et al. 1997). CRH_1 receptors are broadly distributed within the CNS and have a high affinity for CRH. Decreased activity of CRH_1 receptors is associated with reduced anxiety in animal models. CRH_2 receptors are broadly distributed throughout the brain, overlapping topographically with CRH_1 receptors. CRH_2 receptors display a lower affinity for CRH than CRH_1 receptors and likely utilize urocortin as their endogenous ligand. However, in contrast to CRH_1 receptors, reduced activity of CRH_2 receptors results in increased anxiety in animal models.

Injection of CRH into the CNS of laboratory animals initiates changes in the activity of the autonomic nervous system that result in the elevation of peripheral catecholamines, reduced gastrointestinal activity, increased heart rate, and elevated blood pressure. Furthermore, behavioral changes such as disturbed sleep, diminished food intake, reduced grooming, decreased reproductive behavior, and enhanced fear conditioning, similar to those observed in humans with depression, also occur following direct CNS administration of CRH (Dunn and Berridge 1990; Owens and Nemeroff 1991) and are reduced by pretreatment with CRH receptor antagonists (Gutman et al. 2003; Heinrichs et al. 1995).

Corticotropin-Releasing Hormone and HPA Axis Pathophysiology

Cortisol and the dexamethasone suppression test

The DST, a test originally designed to aid in the diagnosis of Cushing's syndrome, was one of the first endocrine challenge tests to be studied in psychiatric patients. Studies of patients with mood disorders using the DST provided some of the first evidence of abnormal HPA axis function in depression (Table 45–1). The DST consists of the administration of a low dose (1 mg) of the synthetic glucocorticoid dexamethasone at 2300 h followed by measurement of plasma cortisol concentrations at two or three time points the following day. Dexamethasone acts at the level of the anterior pituitary corticotrophs to reduce the secretion of ACTH, resulting in a decrease in the synthesis and release of cortisol from the adrenal cortex. Failure to suppress plasma cortisol concentrations after dexamethasone administration suggests impaired feedback regulation and hyperactivity of the HPA axis.

TABLE 45–1. Alterations in hypothalamic-pituitary-adrenal (HPA) axis activity in unipolar depression

Increased corticotropin-releasing hormone (CRH) in cerebrospinal fluid[a,b]
Blunted corticotropin and β-endorphin response to CRH stimulation[a]
Decreased density of CRH receptors in frontal cortex of suicide victims
Diminished hippocampal volume
Enlarged pituitary gland in depressed patients[b]
Enlarged adrenal gland in depressed patients[b] and suicide victims
Increased corticotropin production during depression
Elevated secretion of corticotropin and cortisol in depressed patients with a history of early life stress
Increased cortisol production during depression[a]

Nonsuppression of plasma glucocorticoid, corticotropin, and β endorphin after dexamethasone administration[a]

Increased urinary free cortisol concentrations

[a]State-dependent.

[b]Significantly correlated to postdexamethasone cortisol concentrations.

A large percentage of drug-free patients with major depression fail to suppress secretion of cortisol following administration of dexamethasone, a finding known as dexamethasone nonsuppression (Carroll et al. 1968a), suggesting the use of DST nonsuppression as a biological marker for depression (Carroll 1982). DST nonsuppression status and hypercortisolemia are both common in depression but certainly not universal. Meta-analyses have revealed that DST nonsuppression status is most commonly found in patients with psychotic depression or mixed bipolar states, as previously reported by several investigators (Evans and Nemeroff 1983; Schatzberg et al. 1984) and that DST nonsuppression status generally predicts a more severe course of illness (Arana et al. 1985). Additional data, also procured using meta-analysis, have provided further support to the relationship between hypercortisolemia and psychotic depression as assessed with the DST (Nelson and Davis 1997). Finally, data derived from meta-analysis (S. C. Ribeiro et al. 1993) confirmed that 1) baseline DST status was not predictive of response to treatment, 2) DST nonsuppression status was associated with poor response to placebo, and 3) posttreatment DST nonsuppression was a significant risk factor for relapse and poor outcome, as initially reported by Greden et al. (1980) and confirmed by Nemeroff and Evans (1984). The prognostic utility of the DST with respect to suicide remains unclear. Some data suggest that DST nonsuppression is predictive of future completed suicide (Coryell and Schlesser 2001), whereas other data suggest that it is not (Black et al. 2002).

Substantial rates of DST nonsuppression have been reported in patients with a variety of other DSM Axis I and Axis II diagnoses (Baxter et al. 1984; Gerner and Gwirtsman 1981; Hubain et al. 1986), calling into question its specificity as a diagnostic test. However, the greatest contribution of the DST was to serve as an impetus for subsequent studies exploring the underlying pathophysiology of the HPA axis in depression.

Corticotropin-releasing hormone and depression

A large body of data using markers such as CSF CRH concentrations, postmortem brain CRH concentrations, CRH mRNA expression, and CRH receptor autoradiography has accumulated suggesting that the abnormal activity of the HPA axis often observed in depressed patients (Plotsky et al. 1998) is due, in part, to hypersecretion of CRH (Arborelius et al. 1999). Elevated CSF concentrations of CRH have repeatedly been reported in patients with depression (Hartline et al. 1996; Nemeroff et al. 1984), as well as in combat veterans with posttraumatic stress disorder (PTSD) (Baker et al. 1999; Bremner et al. 1997a). In addition, the transcription (Raadsheer et al. 1995) as well as expression (Raadsheer et al. 1994) of CRH is increased in postmortem tissue in patients with depression. Furthermore, postmortem studies of individuals who have committed suicide have revealed elevated concentrations of CSF CRH (Arato et al. 1989), decreased expression of CRH_1 receptor mRNA within the frontal cortex (Merali et al. 2004), and increased CRH concentrations and decreased density of CRH receptors within the frontal cortex in comparison with control subjects (Merali et al. 2006; Nemeroff et al. 1988). Successful treatment of depression using either electroconvulsive therapy (Nemeroff et al. 1991) or fluoxetine (De Bellis et al. 1993b) has been shown to reduce the high pretreatment concentrations of CSF CRH. By contrast, persistent elevations of CSF CRH in symptomatically improved depressed patients are associated with early relapse of depression (Banki et al. 1992).

Considerable data support the hypothesis that the dysregulation of the HPA axis observed in depression is a state, rather than a trait, phenomenon. In this context, state dependence implies the presence of pathophysiological phenomena that are related to a particular phase of illness rather than

being constitutively present (i.e., trait based). In depressed hypercortisolemic patients, plasma and urinary free cortisol concentrations (Sachar et al. 1970), DST nonsuppression status (Arana et al. 1985), blunting of the ACTH response to CRH infusion (Amsterdam et al. 1988), dexamethasone–CRH test results (Ising et al. 2005; Nickel et al. 2003), hypersecretion of CRH (Nemeroff et al. 1991), and adrenal hypertrophy (Rubin et al. 1995) all normalize following resolution of clinical symptoms.

HPA axis pathophysiology in specific mood disorders

Major depression with psychotic features

Patients with psychotic depression demonstrate hyperactivity of the HPA axis along with the highest rates of DST nonsuppression (Evans et al. 1983; Schatzberg et al. 1983). Distinct patterns of HPA axis abnormalities have been observed in depressed patients with and without psychotic features. Posener et al. (2000) reported that nonpsychotic depressed patients exhibited a lower 24-hour cortisol amplitude compared with depressed patients with psychosis, whereas patients with psychotic features had an increased 24-hour mean corticotropin secretion compared with depressed patients without psychosis. Subsequent studies have also identified disturbances between HPA axis function and the circadian timing system in patients with psychotic depression (Keller et al. 2006). In a study examining the relationship between cognition and the diurnal variation of cortisol in patients with depression, higher afternoon cortisol levels and a higher rate of errors of commission on a test of verbal memory were found in patients with psychotic depression as compared with patients with nonpsychotic depression (Belanoff et al. 2001b; Gomez et al. 2006). Hypercortisolemia has also been associated with cognitive impairment in schizophrenia and schizoaffective disorder as well (Walder et al. 2000). The glucocorticoid antagonist mifepristone (RU-486) has been suggested to be an efficacious treatment for psychotic depression (Belanoff et al. 2001a, 2002; A. H. Young 2006; A. H. Young et al. 2004) as well as treatment-refractory Cushing's disease (Chu et al. 2001).

Nonpsychotic major depression

Depressed patients without psychosis may have either decreased or normal activity of the HPA axis (Posener et al. 2000), whereas depressed patients who have a history of childhood adversity show elevated secretion of ACTH and cortisol in response to a laboratory stress test (Heim et al. 2000) as well as neuroendocrine challenge tests, including the dexamethasone–CRH test (Heim et al. 2001, 2008). Appreciating the presence of childhood trauma in patients with depression may be integral to their treatment because a multisite treatment study found that patients with chronic depression with a history of trauma during childhood responded preferentially to treatment with a form of cognitive-behavioral therapy (CBT) developed for chronic depression compared with the antidepressant nefazodone (Nemeroff et al. 2003). This suggests that particular subtypes of depression may require different approaches to treatment.

Bipolar disorder

Alterations of the HPA axis also have been documented in patients with bipolar affective disorder (Daban et al. 2005; Kiriike et al. 1988) (Table 45–2). Increased HPA axis activity has been associated with mixed manic states (Evans and Nemeroff 1983; R. R. Krishnan et al. 1983; Swann et al. 1992), mania (Godwin et al. 1984; Linkowski et al. 1994), and depression in rapid-cycling patients (Kennedy et al. 1989). In addition, the enhanced salivary cortisol response to waking may represent an ongoing tendency to abnormal cortisol regulation in clinically well, lithium-responsive bipolar patients, indicating the presence of enduring HPA dysregulation (Deshauer et al. 2003). Similarly, abnormal findings using the combined dexamethasone–CRH test have been reported in both remitted and nonremitted patients with bipolar disorder, suggesting its use as a potential trait marker in bipolar disorder (Watson et al. 2004, 2005). Furthermore, the offspring of parents with bipolar disorder have increased basal HPA axis activity through normal psychosocial stress reactivity (Ellenbogen et al.

2004, 2006). One molecular target for heritable predisposition to altered HPA reactivity and possibly mood disorder is the GR. Both unipolar and bipolar depressed patients as well as the first-degree relatives of bipolar probands demonstrate reduced expression of GR-α mRNA (Matsubara et al. 2006) as well as alteration of a number of intracellular signaling cascades in lymphocytes (Spiliotaki et al. 2006).

TABLE 45–2. Alterations in hypothalamic-pituitary-adrenal (HPA) axis activity in bipolar disorder
Increased plasma cortisol concentrations
Blunted diurnal variation of plasma cortisol concentrations
Increased cortisol in cerebrospinal fluid
Nonsuppression of plasma glucocorticoid concentrations after dexamethasone administration

Hypothalamic-Pituitary-Thyroid Axis

Functional Organization of the HPT Axis

The discovery of the tripeptide thyrotropin-releasing hormone (TRH) in 1970 (Burgus et al. 1970; Nair et al. 1970) facilitated expanded understanding of the regulation of the HPT axis. Like CRH, TRH is widely distributed within extrahypothalamic regions of the brain where it acts as a neurotransmitter quite distinct from its role as a hypothalamic–hypophysiotropic hormone. Also similar to CRH, TRH is released by parvocellular neurons of the hypothalamic paraventricular nucleus, whose fibers project to the median eminence where they secrete TRH into the hypothalamo-hypophyseal portal system (Greer 1952; Swanson and Kuypers 1980). TRH is then transported to the anterior pituitary where it acts upon TRH receptors located on pituitary thyrotrophs to cause the release of thyroid-stimulating hormone (TSH), also known as thyrotropin. TSH released from the pituitary is transported within the systemic circulation to the thyroid gland where activation of TSH receptors results in increased iodine uptake, follicle cell metabolism, and the release of the two major thyroid hormones, T_3 and thyroxine (T_4). Once released into the general circulation, T_3 and T_4 are bound to plasma proteins, including transthyretin and thyroxine-binding globulin. Thyroid hormones regulate a wide variety of metabolic activities and provide negative feedback at the level of the hypothalamus and pituitary to regulate, respectively, the release of TRH and TSH.

Mood Disorders and Pathophysiology of the HPT Axis

Unipolar depression

Several lines of inquiry are indicative of dysregulation of the HPT axis in depression (Table 45–3). Elevated CSF TRH concentrations have been reported in depressed patients (Banki et al. 1988; Kirkegaard et al. 1979), although there is one discordant report (Roy et al. 1994). In addition, reduction of the mean and peak amplitudes of the 24-hour TSH secretion cycle in depressed patients suggests the presence of chronobiological dysfunction within the HPT axis (Duval et al. 1990, 1996). Furthermore, a multitude of studies using a standardized TRH stimulation test in depressed patients with normal thyroid function have consistently revealed a blunted TSH response (Esposito et al. 1997; Nemeroff and Evans 1989), suggesting downregulation of pituitary TRH receptors perhaps in response to hypersecretion of hypothalamic TRH. Alternatively, thyroid hormones may not be effectively transported to the CNS in patients with depression. Reduced CSF concentrations of transthyretin, which is essential for the transport of thyroid hormone across the blood–brain barrier, have been reported in patients with depression (Hatterer et al. 1993; G. M. Sullivan et al. 1999). Clinically, there have been reports that thyroid hormone supplementation, primarily with T_3, is an effective augmentation strategy in the treatment of depression (Aronson et al. 1996; Iosifescu et al. 2005), although again discordant reports have appeared (Appelhof et al. 2004). Recently, a double-blind,

placebo-controlled multisite trial of T_3 augmentation of sertraline treatment of depression demonstrated clear efficacy of this augmentation strategy (Cooper-Kazaz et al. 2007). Our group failed to demonstrate any advantage of T_3 coadministration with sertraline compared with placebo in depressed patients in terms of speed of onset or magnitude of antidepressant response (Garlow et al. 2007). One major difference between these two studies is the dose of sertraline; in the former, the mean dose was considerably lower than in the latter.

TABLE 45–3. Alterations in hypothalamic-pituitary-thyroid (HPT) axis activity in unipolar depression

Increased thyrotropin-releasing hormone (TRH) in cerebrospinal fluid
Decreased nocturnal plasma thyroid-stimulating hormone (TSH) concentrations
Blunted or exaggerated TSH response to TRH stimulation
Decreased ΔΔTSH (difference between 11:00 P.M. change in TSH [ΔTSH] and 8:00 A.M. ΔTSH after TRH administration)
Presence of antithyroid microsomal and/or antithyroglobulin antibodies

Depressed patients have also been repeatedly shown to have a higher-than-expected occurrence of symptomless autoimmune thyroiditis (Table 45–4), as defined by the abnormal presence of circulating thyroid antimicrosomal or antithyroglobulin antibodies (M. S. Gold et al. 1982; Nemeroff et al. 1985). Depressed women with symptomless autoimmune thyroiditis and diffuse nontoxic goiter were more likely to have a reduced response to TRH administration than were depressed women without thyroid disease (Bunevicius et al. 1996). Moreover, the incidence of symptomless autoimmune thyroiditis is higher (i.e., 50%) in depressed patients who are DST nonsuppressors (Haggerty et al. 1987). These patients may be designated as having grade IV hypothyroidism; they have positive antithyroid antibodies but normal T_3, T_4, TSH, and TRH-induced TSH response (Haggerty et al. 1990).

TABLE 45–4. Grades of hypothyroidism

Grade	T_3, T_4	Basal TSH	TSH response to TRH	Antithyroid antibodies
I	Decreased	Increased	Increased	Often present
II	Normal	Increased	Increased	Often present
III	Normal	Normal	Increased	Often present
IV	Normal	Normal	Normal	Present

Note. T_3 = triiodothyronine; T_4 = thyroxine; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone.

Bipolar disorder

Abnormalities of the HPT axis (e.g., hypothyroidism) also have been reported in patients with bipolar disorder (Table 45–5), as indicated by an exaggerated TSH response to TRH and elevated basal plasma concentrations of TSH (Haggerty et al. 1987; Loosen and Prange 1982). In fact, two groups have reported a higher prevalence rate of hypothyroidism (grades I, II, and III) in bipolar patients who experience rapid cycling of their mood than in bipolar patients who do not (Bauer and Whybrow 1990a; Cowdry et al. 1983). Other abnormalities of the thyroid axis, including a blunted TSH response to TRH, a blunted or absent nocturnal surge in concentrations of plasma TSH (Sack et al. 1988; Souetre et al. 1988), and a higher-than-expected prevalence of antithyroid microsomal or antithyroglobulin antibodies (Lazarus et al. 1986; Myers et al. 1985), have been documented in bipolar patients (see Table 45–4). The presence of antithyroid antibodies often observed in patients with bipolar disorder is apparently not a result of lithium treatment (Kupka et al. 2002), but lithium may exacerbate the process (Calabrese et al. 1985; Dang and Hershman 2002), and autoimmune

thyroiditis may form part of the component genetic vulnerability for bipolar disorder (Vonk et al. 2007). Thyroid hormone supplementation has been suggested to be an effective adjunctive treatment for bipolar disorder because hypothyroidism is frequently observed in patients with bipolar disorder (Bauer and Whybrow 1990a, 1990b; Cowdry et al. 1983). As predictors of treatment response, lower free T_4 indices and higher plasma TSH concentrations have been significantly associated with longer times to remission in patients with bipolar disorder (Cole et al. 2002; Fagiolini et al. 2006).

TABLE 45–5. Alterations in hypothalamic-pituitary-thyroid (HPT) axis activity in bipolar disorder

Blunted plasma thyroid-stimulating hormone (TSH) response to thyrotropin-releasing hormone (TRH) stimulation
Exaggerated plasma TSH response to TRH stimulation
Blunted or absent nocturnal surge in plasma TSH concentration
Presence of antithyroid microsomal and/or antithyroglobulin antibodies

Hypothalamic-Pituitary–Growth Hormone Axis

Functional Organization of the HPGH Axis

Growth hormone (GH) is synthesized and secreted from the somatotrophs of the anterior pituitary. Its secretion is modulated by two hypothalamic–hypophysiotropic hormones, growth hormone–releasing hormone (GHRH, or growth hormone–releasing factor [GRF]) and somatostatin (growth hormone release–inhibiting hormone [GHRIH], or somatotropin release–inhibiting factor [SRIF]) as well as by the classical monoamine neurotransmitters (e.g., DA, NE, and 5-HT) that innervate the GRF-containing neurons. Located primarily in the arcuate nucleus of the hypothalamus, GRF stimulates the synthesis and release of GH (Flament-Durand 1980). Inhibition of GH release is mediated primarily by SRIF, which is found predominantly in the paraventricular nucleus of the hypothalamus (Flament-Durand 1980). However, unlike GRF, SRIF is also widely distributed in extrahypothalamic brain regions, including the cerebral cortex, hippocampus, and amygdala. Both GRF and SRIF are released from nerve terminals in the median eminence and transported via the hypothalamic–hypophysiotropic portal system to act on the GH-producing somatotrophs of the anterior pituitary.

Release of GH is stimulated by L-dopa (Boyd et al. 1970), a DA precursor, and by apomorphine, a centrally active DA receptor agonist (Lal et al. 1975). GH release also occurs following the administration of the 5-HT precursors L-tryptophan and 5-hydroxytryptophan (5-HTP) (Imura et al. 1973; Muller et al. 1974). The 5-HT receptor antagonists methysergide and cyproheptadine attenuate the GH response to hypoglycemia (Toivola et al. 1972). Under normal basal conditions, GH is secreted in pulses that are highest during the initial hours of the night (Finkelstein et al. 1972).

Mood Disorders and Pathophysiology of the HPGH Axis

Mood disorders have been reported to be associated with multiple alterations in GH secretion (Table 45–6). Nocturnal GH secretion is diminished in depressed patients (Schilkrut et al. 1975), whereas in both unipolar and bipolar depressed patients, daylight GH secretion is exaggerated (Mendlewicz et al. 1985). Furthermore, multiple studies have reported a marked attenuation of the GH response to clonidine, an α_1-adrenergic receptor agonist, and, to a lesser extent, apomorphine, a D_2 and D_3 dopamine receptor agonist, in depressed and bipolar patients (Charney et al. 1982; Checkley et al. 1981; Matussek et al. 1980; Siever et al. 1982). Blunting of noradrenergic agonist–stimulated GH secretion has been observed during mania as well (Dinan et al. 1991). Dexamethasone-induced GH secretion is also significantly decreased in depressed patients (Thakore and Dinan 1994).

TABLE 45–6. Alterations in hypothalamic–growth hormone axis activity in depression

Decreased nocturnal growth hormone secretion in depressed patients

Increased daylight growth hormone secretion (unipolar and bipolar depressed patients)

Decreased growth hormone response to challenge with clonidine and apomorphine

Decreased growth hormone response to growth hormone–releasing factor

Decreased somatostatin in cerebrospinal fluid that is inversely correlated with postdexamethasone plasma cortisol concentrations

GH response to stimulation by GRF has been scrutinized in depressed patients in a limited number of studies, and the results are somewhat discordant. Three research groups have reported a diminished GH response to GRF in depressed patients (Contreras et al. 1996; Lesch et al. 1987a, 1987b; S. C. Risch et al. 1988). However, K. R. Krishnan et al. (1988) found minimal differences between depressed patients and nondepressed control subjects in GH plasma concentrations following GRF stimulation. These conflicting findings could be explained by various other factors that can influence the GH response to GRF, including gender, age, menstrual cycle, plasma glucocorticoid or somatomedin concentrations, and body weight (Casanueva et al. 1988, 1990; K. R. Krishnan et al. 1988).

Somatostatin (SRIF), the tetradecapeptide hypothalamic GHRIH, inhibits secretion of both CRH and corticotropin (M. R. Brown et al. 1984; Heisler et al. 1982; Richardson and Schonbrunn 1981). In several studies, CSF SRIF concentrations have been reported to be reduced in depressed patients (Agren and Lundqvist 1984; Bissette et al. 1986; Gerner and Yamada 1982; Rubinow et al. 1983) and are inversely correlated with postdexamethasone plasma cortisol concentrations (Rubinow 1986). In fact, exogenous glucocorticoids reduce CSF SRIF concentrations (Wolkowitz et al. 1987). Glucocorticoids likely inhibit the activity of somatostatinergic neurons within the anterior and paraventricular hypothalamus because dexamethasone administration stimulates GH release in nondepressed control subjects (Casanueva et al. 1990).

Hypothalamic-Pituitary-Gonadal Axis

Functional Organization of the HPG Axis

Like the HPA and HPT axes, the HPG axis is organized in a "hierarchical" fashion. Driven by a pulse generator in the arcuate nucleus of the hypothalamus, gonadotropin-releasing hormone (GnRH) secretion occurs in a pulsatile fashion (Knobil 1990). GnRH acts upon the gonadotrophs in the anterior pituitary, releasing luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Midgley and Jaffe 1971). Fluctuations in LH concentrations in the peripheral circulation are used as an indirect measure of GnRH secretory pulses (Clarke and Cummins 1982) largely because peripheral plasma concentrations of GnRH, like those of TRH and CRH, cannot easily be reliably measured (Meller et al. 1997). In the follicular phase of the menstrual cycle, LH pulses of nearly constant amplitude occur with regular frequency, approximately every 1–2 hours (Reame et al. 1984). In the luteal phase, LH pulse amplitude (reflecting GnRH secretion) is more variable, with pulse frequency declining to one pulse every 2–6 hours (Jaffe et al. 1990). Through negative feedback, gonadal steroids inhibit the secretion of GnRH from the hypothalamus, as well as the secretion of LH and FSH from the anterior pituitary. GnRH secretion is also inhibited by CRH (Jaffe et al. 1990) and β-endorphin (Ferin and Van de Wiele 1984).

Mood Disorders and Pathophysiology of the HPG Axis

Despite the higher incidence of depression in women and the increased occurrence of depression during and after menopause, data are relatively limited on HPG axis function in patients with mood disorders (Table 45–7).

TABLE 45–7. Alterations of the hypothalamic-pituitary-gonadal axis in depression
Decreased plasma luteinizing hormone concentrations in depressed postmenopausal women
Increased amplitude of nonrhythmic luteinizing hormone pulses in depressed premenopausal women
Decreased luteinizing hormone response to gonadotropin-releasing hormone challenge test in depressed postmenopausal women
DST nonsuppression more common in depressed premenopausal women

In early studies, no significant differences were reported in plasma concentrations of LH and FSH in depressed postmenopausal women compared with nondepressed matched control subjects (Sachar et al. 1972). However, in a later study, plasma LH concentrations were reported to be decreased in depressed postmenopausal women compared with matched control subjects (Brambilla et al. 1990). Furthermore, depressed *pre*menopausal women show increased amplitude pulses of LH in a nonrhythmic fashion in comparison with nondepressed women of similar age (Meller et al. 1997).

Rather than measure baseline plasma levels of the pituitary gonadotropins in depressed patients, other investigators have studied the response of the pituitary to exogenous administration of GnRH. Normal LH and FSH responses to a supraphysiological dose of GnRH (i.e., 250 μg) have been reported in depressed male and female (pre- and postmenopausal) patients (Winokur et al. 1982), whereas a decreased LH response to a lower dose of GnRH (150 μg) has been reported in pre- and postmenopausal depressed patients (Brambilla et al. 1990). In a depressed cohort including both sexes (analyses of men and premenopausal vs. postmenopausal depressed women were not separately performed), no change in baseline or TRH/luteinizing hormone–releasing hormone (LHRH)–stimulated LH or FSH concentrations (200 μg TRH and 100 μg LHRH combined, intravenously) was observed (Unden et al. 1988). Notably, plasma LH concentrations have been reported to be increased in individuals who have recovered from a manic episode—possibly a trait phenomenon (Whalley et al. 1987).

Many measures of HPA, HPT, and human GH axis activity do not appear to fluctuate predictably during the menstrual cycle (Leibenluft et al. 1994; E. A. Young et al. 2001). However, estrogen and progesterone do exert important actions on certain components of the HPA axis in women. Estrogen stimulates production of corticosteroid-binding globulin, thereby decreasing concentrations of unbound and physiologically available cortisol, whereas progesterone functions as a glucocorticoid receptor antagonist. In postmenopausal depressed women, DST nonsuppression is more common and occurs with lower plasma cortisol concentrations in comparison with premenopausal depressed women. Thus, ovarian steroids may play a protective role in depressed premenopausal women against elevated circulating glucocorticoid levels as might occur during episodes of major depression (E. A. Young 1995). It is interesting to note that lower follicular-phase mean plasma estradiol levels and a shorter half-life of LH have been reported among depressed women compared with age-matched control subjects (E. A. Young et al. 2000). Additional research on the HPG axis in depression is warranted.

NEUROTRANSMITTER SYSTEMS

Monoaminergic Neurotransmitters

Serotonin

5-HT is an indoleamine neurotransmitter derived enzymatically from tryptophan and produced in neurons of the rostral and caudal raphe nuclei. Projections originating from the raphe are widespread and innervate a variety of forebrain structures including the hypothalamus, amygdala, basal ganglia, thalamus, hippocampus, cingulate cortex, and prefrontal cortex (Azmitia and Gannon 1986). Fourteen 5-HT receptors, localized on both pre- and postsynaptic elements, have now been identified and

include members of the ionotropic as well as metabotropic receptor gene superfamilies (Baez et al. 1995). Following release from synaptic terminals, 5-HT is removed from extracellular fluid by the 5-HTT, located on the presynaptic terminal, and is either repackaged into synaptic vesicles or degraded by monoamine oxidase (MAO).

Several lines of evidence (Table 45–8) suggest a role for deficient 5-HT signaling in depression (Owens and Nemeroff 1994; Purselle and Nemeroff 2003; S. C. Risch and Nemeroff 1992; Vergne and Nemeroff 2006). Low CSF concentrations of the major metabolite of serotonin, 5-HIAA, have repeatedly been found in depressed (Åsberg et al. 1976a, 1976b) and suicidal (Åsberg et al. 1976b; Mann et al. 1996) patients. In addition, acute experimental depletion of tryptophan in patients with remitted depression who had responded to SSRIs has been found to rapidly precipitate recurrence of depression (Booij et al. 2002; K. A. Smith et al. 1997). 5-HTT binding, as measured by functional brain imaging techniques, is reduced in the CNS of depressed patients (Malison et al. 1998; Oquendo et al. 2007; Perry et al. 1983) as well as in postmortem tissue of individuals who have committed suicide (Mann et al. 2000; Stanley et al. 1982), although discordant findings have appeared (Little et al. 1997).

TABLE 45–8. Alterations in the serotonergic system in depression

Decreased plasma tryptophan concentrations
Decreased cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA)
Increased CSF 5-HIAA in psychotic depression
Increased postsynaptic 5-HT_2 receptors
Decreased brain and platelet [^{3}H]imipramine binding
Decreased brain and platelet [^{3}H]paroxetine binding
Blunted prolactin response to fenfluramine
Decreased serotonin transporter (5-HTT) binding in the midbrain of depressed patients (on [^{123}I]- β-CIT)

Note. [^{123}I]-β-CIT = ^{123}I-labeled 2-β-carbomethoxy-3-β-(4-iodophenyl) tropane.

Although there are 14 5-HT receptor subtypes, both 5-HT_{2A} and 5-HT_{2C} have arguably received the most scrutiny in depression (Stahl 1998), although abnormalities in other 5-HT receptor subtypes in depressed patients have been identified, most notably the 5-HT_{1A} receptor (Drevets et al. 1999). Indeed, an increased density of 5-HT_2 receptors is found in the prefrontal cortex and amygdala of untreated suicide victims compared with control subjects (Hrdina et al. 1993), suggesting a possible compensatory upregulation of 5-HT_2 receptor density as a consequence of reduced synaptic concentrations of 5-HT. Similarly, elevation of 5-HT_2 receptor binding on platelets differentiates suicidal from nonsuicidal depressed patients (Bakish et al. 1997), and a reduction in platelet 5-HT_2 receptor binding in antidepressant-treated patients is associated with clinical improvement in depression (Biegon et al. 1987, 1990) in antidepressant-treated patients. Other investigators, however, have reported discordant results with respect to platelet 5-HT_2 receptor binding (Bakish et al. 1997), as well as CNS 5-HT_2 receptor binding (Biver et al. 1997) as a marker of improvement of depressive symptoms or as a marker of depression itself (Meyer et al. 1999). Finally, and perhaps most importantly, a large body of data supports the use of SSRIs, which act primarily by increasing synaptic levels of 5-HT, as first-line agents in the treatment of depression (Nemeroff 2007).

Norepinephrine

NE is a catecholamine neurotransmitter derived enzymatically from tyrosine and produced in neurons of the locus coeruleus (LC) and, to a lesser extent, the lateral tegmental nuclei. Projections originating from the LC innervate a variety of forebrain structures including the cerebral cortex, thalamus,

cerebellar cortex, hippocampus, hypothalamus, and amygdala (Moore and Bloom 1979). NE acts through activation of alpha (α) and beta (β) adrenergic receptors. Following release from central synaptic terminals, NE is taken up into the presynaptic element by the norepinephrine transporter (NET) and is either repackaged into synaptic vesicles or degraded by MAO. Within the peripheral nervous system, NE is released from terminals of the sympathetic nervous system, as well as from the adrenal medulla.

Although the database may not be as large or diverse as for 5-HT, findings (Table 45–9) derived from studies of NE turnover, experimental NE depletion, and antidepressant efficacy implicate NE in the pathophysiology and treatment of depression (Ressler and Nemeroff 2001). Elevated CSF concentrations of the major NE metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG), have been observed in depressed patients, as well as in those with mania and schizoaffective disorder, in some studies (Schildkraut 1965) but not others (De Bellis et al. 1993a). In the latter study, MHPG levels were found to decline in the subset of patients with depression following treatment with an SSRI, fluoxetine, and subsequent symptom reduction (De Bellis et al. 1993a). Additional studies have confirmed that successful SSRI treatment of depression results in decreased CSF MHPG concentrations (Sheline et al. 1997). In contrast, concentrations of NE and its metabolites have been found to be increased in the plasma (Louis et al. 1975; Roy et al. 1988; Veith et al. 1994; Wyatt et al. 1971) and urine (Roy et al. 1986, 1988) of depressed patients. Depressed patients as a group demonstrate higher baseline plasma NE concentrations compared with control subjects and following orthostatic challenge; melancholic depressed patients exhibit higher plasma NE concentrations than do nonmelancholic depressed patients or healthy control subjects (Roy et al. 1987). Furthermore, depressed DST nonsuppressors have higher basal and cold-stimulated plasma NE levels than do depressed DST suppressors (Roy et al. 1987), suggesting that differences in depressive subtype or severity of mood symptoms may increase noradrenergic activity. Similar to the above-described studies of SSRI treatment on concentrations of CSF MHPG, treatment of depressed patients with TCAs results in decreased plasma (Charney et al. 1981) and urinary concentrations of (Golden et al. 1988; M. Linnoila et al. 1982, 1986) NE metabolites. The validity of plasma or urine concentrations of NE or its metabolites compared with CSF measures as an index of CNS NE circuit activity has long been a subject of intense debate.

TABLE 45–9. Alterations in the noradrenergic system in depression

Increased or decreased 3-methoxy-4-hydroxyphenylglycol (MHPG)
Increased α_2-adrenergic binding in platelets
Blunted growth hormone response to clonidine
Increased β-adrenergic receptors in postmortem brain of suicide victims
Downregulation of β-adrenergic receptors after treatment with antidepressants

In addition to data on NE and NE metabolite turnover, experimental depletion of NE in depressed patients treated with an NE reuptake inhibitor (e.g., desipramine) can precipitate relapse of depression (Charney 1998), as can experimental depletion of catecholamines (which depletes both NE and DA) in euthymic, unmedicated patients with a history of depression (R. M. Berman et al. 1999). Furthermore, suicide victims have been found to exhibit increased activity of the rate-limiting enzyme in NE synthesis, tyrosine hydroxylase (TH), within the LC in postmortem tissue studies (Ordway 1997), suggestive of high NE turnover in severely depressed patients with compensatory upregulation of TH. Endocrine challenge tests conducted in unmedicated depressed patients using clonidine, an α_2-adrenergic agonist, demonstrate blunting of the normally robust GH response to such adrenergic stimulation (Matussek et al. 1980; Siever et al. 1982, 1992). Finally, a large body of clinical data supports the efficacy of relatively selective NE reuptake inhibitors, such as reboxetine and desipramine, in the treatment of depression (Nemeroff 2007).

Dopamine

DA, the direct precursor to NE, is a catecholamine neurotransmitter in its own right. Within the CNS, dopaminergic neurons are organized into three major systems anatomically (Moore and Bloom 1978): 1) the nigroneostriatal system, which plays a key role in the regulation of movement, originates within the pigmented cells of the substantia nigra pars compacta, and its fibers project rostrally into the corpus striatum; 2) the mesolimbic/mesocortical system is a key regulator of limbic and cortical neural activity and originates within the A10 cell group of the ventral tegmental area (VTA), and its fibers project to numerous limbic structures (mesolimbic system) and the prefrontal cortex (mesocortical system); 3) the tuberoinfundibular system originates within the A12 cells of the arcuate nucleus of the hypothalamus, and its fibers project to the median eminence where released DA acts at the anterior pituitary to inhibit the secretion of prolactin. DA acts through several subtypes of G protein–coupled receptors and, similar to other monoamines, is taken up by the dopamine transporter (DAT) on the presynaptic terminal. Like 5-HT and NE, DA is catabolized by MAO if not repackaged into vesicles for subsequent release.

Dopamine and mood disorders

DA has been implicated in the pathogenesis of depression (Table 45–10) on the basis of metabolite and radioligand data both in postmortem tissue and in patients using functional brain imaging. CSF concentrations of the major DA metabolite homovanillic acid (HVA) (Reddy et al. 1992; Roy et al. 1992) as well as urinary concentrations of 3,4-dihydroxyphenylacetic acid (DOPAC) (Roy et al. 1986) are decreased in patients with depression and may also be associated with suicidal behavior (Roy et al. 1992). In addition, a recent report confirmed and extended the original observations of M. Martinot et al. (2001), in which altered dopaminergic activity, as measured with [^{18}F]fluorodopa positron emission tomography (PET), within the caudate, putamen, and nucleus accumbens of depressed patients with affective flattening and psychomotor retardation was noted (Bragulat et al. 2007). Furthermore, PET studies of the DAT as well as of radiolabeled DOPA uptake in depressed patients (Meyer et al. 2001), in concert with postmortem autoradiography studies in suicide victims (Klimek et al. 2002), collectively indicate reduced activity of DA neurons in depressed patients. This is concordant with the relatively high rate of comorbidity of depression in patients with Parkinson's disease (McDonald et al. 2003), a disorder characterized by DA neuronal degeneration and depression. Finally, preliminary data suggest that $DA_{2/3}$ receptor agonists such as pramipexole or ropinirole may be effective in the treatment of bipolar depression (Goldberg et al. 2004; Zarate et al. 2004b).

TABLE 45–10. Alterations in the dopaminergic system in depression

Decreased CSF concentrations of homovanillic acid and urinary concentrations of 3,4-dihydroxyphenylacetic acid in patients with depression
Reduced dopaminergic activity within the caudate, putamen, and nucleus accumbens of depressed patients with affective flattening and psychomotor retardation as measured by [^{18}F]- fluorodopa PET imaging
Reduced dopaminergic activity in the CNS of depressed patients (PET imaging) and suicide victims (postmortem autoradiography)
Decreased levels of serum dopamine β-hydroxylase activity, higher concentrations of plasma dopamine and increased CSF concentrations of homovanillic acid in patients with psychotic depression

Note. CNS = central nervous system; CSF = cerebrospinal fluid; PET = positron emission tomography.

Dopamine beta-hydroxylase and mood disorders

The enzyme dopamine β-hydroxylase (DBH) catalyzes the conversion of DA to NE. Preclinical research

suggests a major role for DBH in the biological response to antidepressants (Cryan et al. 2004). Compared with nonpsychotic depressed patients, depressed patients with psychotic symptoms have been reported to have lower levels of serum DBH activity and higher concentrations of plasma DA, as well as increased concentrations of CSF and plasma HVA (Aberg-Wistedt et al. 1985; Devanand et al. 1985; Schatzberg et al. 1985a; Sweeney et al. 1978).

Several studies have measured DBH activity in major psychiatric disorders, including schizophrenia and mood disorders. However, results generally have been consistent only for patients with unipolar psychotic depression, who have been reported to have reduced serum DBH activity. Sapru et al. (1989) reported lower serum DBH activity in patients with psychotic major depression compared with control subjects, with no differences between patients with schizophrenia, bipolar disorder (manic phase), or nonpsychotic major depression. Indeed, diminished DBH activity has been hypothesized to be a risk factor for developing psychotic depression, and investigations into allelic variants influencing DBH activity are ongoing (Cubells and Zabetian 2004; Cubells et al. 2002).

Several studies have suggested that dopaminergic activity may be increased, at least partially, as a result of increased adrenocortical activity. Glucocorticoids induce tyrosine hydroxylase, the rate-limiting enzyme in the biosynthesis of DA and NE. The administration of dexamethasone can significantly increase plasma free DA and HVA concentrations in healthy control subjects (Rothschild et al. 1984; Wolkowitz et al. 1985), and the administration of corticosterone or dexamethasone to rats significantly increases central dopaminergic activity (Rothschild et al. 1985; Wolkowitz et al. 1986). Schatzberg et al. (1985a) have hypothesized that the glucocorticoids' enhancement of dopaminergic activity may underlie the development of psychosis in depressed patients.

Monoamine Oxidase

Platelet MAO activity has been studied as a possible biological marker in mood disorders (Table 45–11). Bipolar probands and their relatives have been reported to exhibit decreased platelet MAO activity in comparison with unipolar patients or control subjects (Leckman et al. 1977; Samson et al. 1985). Reduced platelet MAO activity is found primarily in bipolar I, not in bipolar II, subjects (Samson et al. 1985). Although studies have suggested that MAO activity is under strong genetic control and is linked to affective pathology, these results have not been widely replicated (Maubach et al. 1981). Interestingly, Schatzberg et al. (1987) reported that MAO activity was significantly higher in patients with psychotic depression than in patients with nonpsychotic depression or in healthy control subjects.

TABLE 45–11. Alterations of monoamine oxidase (MAO) activity in depression

Platelet MAO activity higher in patients with psychotic depression compared with nonpsychotic depressed patients and healthy control subjects
High platelet MAO activity correlated with elevated urinary free cortisol and DST nonsuppression
Elevated MAO-A activity within the CNS of depressed patients as measured by PET imaging

Note. CNS = central nervous system; DST = dexamethasone suppression test; PET = positron emission tomography.

High platelet MAO activity has been found to correlate with elevated urinary free cortisol concentrations and DST nonsuppression (Agren and Oreland 1982; Schatzberg et al. 1985b). This association between high platelet MAO activity and DST nonsuppression has been replicated by several groups (Meltzer et al. 1988; Pandey et al. 1992). Recently, PET methods have been used to reveal elevated MAO-A activity within the CNS of depressed patients relative to nondepressed patients, suggesting that intracerebral elevations of MAO-A may contribute to depression (Meyer et al. 2006).

Excitatory and Inhibitory Amino Acid Neurotransmitters

Glutamate

Glutamate is the major excitatory neurotransmitter within the CNS and is critically involved in learning and memory formation by both its release as a conventional neurotransmission and its role in the regulation of synaptic plasticity (Derkach et al. 2007; Gillespie and Ressler 2005; Rao and Finkbeiner 2007). These effects are mediated by a large variety of glutamate receptor subtypes that have been identified. They include three major groups of excitatory ionotropic receptors—the *N*-methyl-D-aspartate (NMDA) receptor, the α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor, and the kainate receptor—and a group of metabotropic glutamate receptors (mGluRs).

Increasing evidence suggests a role for glutamate in the biology of mood disorders (Table 45–12) (Kugaya and Sanacora 2005). Several investigators have reported elevated levels of either serum or plasma glutamate concentrations in depressed patients (Altamura et al. 1993; J. S. Kim et al. 1982; Mauri et al. 1998), although discordant results have also been reported (Maes et al. 1998). Whether circulating glutamate levels are in any way representative of CNS glutamatergic function remains unclear. A reduced density of NMDA–glycine binding sites within the brains of both suicide victims (Nowak et al. 1995) and patients with major depression or bipolar disorder has been reported (Nudmamud-Thanoi and Reynolds 2004). In addition, reduced neuronal nitric oxide synthase immunoreactivity (Karolewicz et al. 2004) and elevated concentrations of the glutamate receptor subunit, NR2C (Karolewicz et al. 2005), have been reported in the locus coeruleus of depressed patients indicating substantial alterations in glutamatergic tone.

TABLE 45–12. Alterations of the glutamatergic system in depression and bipolar disorder

Reduced density of NMDA/glycine binding sites within the brains of suicide victims and patients with major depression and bipolar disorder
Reduced neuronal nitric oxide synthase immunoreactivity within the locus coeruleus of depressed patients
Elevated concentrations of the glutamate receptor subunit, NR2C, within the locus coeruleus of depressed patients

Note. NMDA = *N*-methyl-D-aspartate.

Several agents that either directly or indirectly modulate glutamatergic neurotransmission have been reported to exert therapeutic effects in patients with depression. Nearly 50 years ago, the NMDA partial agonist D-cycloserine (Hood et al. 1989), originally used as an antibiotic in the treatment of tuberculosis, was reported to be effective in the treatment of the vegetative symptoms of depression in patients with tuberculosis (Crane 1959, 1961). D-Cycloserine has also been found to be effective as an adjunctive treatment for behavior therapy in patients with anxiety disorders (Davis et al. 2006; Hofmann et al. 2006; Ressler et al. 2004). Anecdotal reports (Goforth and Holsinger 2007; Kudoh et al. 2002) and placebo-controlled studies (R. M. Berman et al. 2000) have suggested that the NMDA receptor antagonist ketamine may also have efficacy in the treatment of depression. Lamotrigine is an anticonvulsant believed to inhibit the release of glutamate through actions on several different ion channels. It is effective in the prevention of depressive episodes in patients with bipolar disorder (Bowden et al. 2003; Calabrese et al. 1999, 2003; G. M. Goodwin et al. 2004). Finally, riluzole, a purported modulator of glutamatergic neurotransmission (Doble 1996; Iwasaki et al. 2002), may be effective in the treatment of depression (Sanacora et al. 2007; Zarate et al. 2004a, 2005).

Gamma-Aminobutyric Acid

γ-Aminobutyric acid (GABA) functions as the major inhibitory neurotransmitter within the CNS (Akerman and Cline 2007; Mehta and Ticku 1999; Michels and Moss 2007; Schousboe and Waagepetersen 2007). GABA receptors have been identified throughout the CNS; in addition to its role

as a neurotransmitter, GABA also plays a central role during development and neurogenesis (Barker et al. 1998). GABA is a major regulator of many CNS functions and affects a variety of other neurotransmitter systems as well in facilitating the interplay of both "fast" and "slow" synaptic transmission (Greengard 2001).

Three types of GABA receptors, $GABA_A$, $GABA_B$, and $GABA_C$, have been identified. $GABA_A$ receptors are ionotropic receptors coupled to chloride ion channels and are associated with benzodiazepine binding sites (Mehta and Ticku 1999; Michels and Moss 2007). $GABA_B$ receptors, activated by drugs such as baclofen, are metabotropic receptors associated with G proteins and the regulation of potassium channels (Kornau 2006; Ulrich and Bettler 2007). $GABA_C$ receptors, the least common form of GABA receptor, are ionotropic receptors and have been found within the midbrain and retina (Enz 2001; Johnston et al. 2003).

There is some evidence that GABAergic neurotransmission may be altered in mood disorders (Table 45–13) (Kugaya and Sanacora 2005; Sanacora and Saricicek 2007; Tunnicliff and Malatynska 2003). The role of the GABAergic system in the pathophysiology of certain forms of epilepsy has been extensively studied, as has its role in the mechanism of action of antiepileptic drugs (White et al. 2007). The anticonvulsants valproic acid and carbamazepine were serendipitously noted to have a mood-stabilizing effect, decreasing the intensity and frequency of manic and perhaps depressive phases of bipolar disorder. All antimanic agents (including lithium) have been suggested to stabilize mood in part by increasing GABAergic transmission, leading to the hypothesis that a relative GABA deficiency plays a role in mania (Bernasconi 1982).

TABLE 45–13. Alterations of the GABAergic system in depression

Cerebrospinal fluid GABA concentrations are lower in depressed patients compared with nondepressed control subjects.
Healthy first-degree relatives of patients with a history of major depression have lower plasma concentrations of GABA compared with subjects without such a family history.

Note. GABA = γ-aminobutyric acid.

B. I. Gold et al. (1980) reported that CSF GABA concentrations in depressed patients were significantly lower than in nondepressed control subjects (this finding has been replicated in several studies); GABA plasma concentrations are reduced in depressed patients as well (Petty and Schlesser 1981; Petty and Sherman 1984). Honig et al. (1988) reported that GABA concentrations in brain tissue from patients undergoing cingulotomy for intractable depression were inversely correlated with severity of depression. Healthy subjects with a first-degree relative with a history of major depression appear to have lower plasma GABA concentrations in comparison with subjects without such a family history (Bjork et al. 2001). Of note, low plasma concentrations of GABA are not specific to patients with mood disorders, as they have also been observed in patients with alcoholism (Petty 1994).

Acetylcholine

In the 1970s, Janowsky et al. (1972) proposed that a relative increase or decrease in CNS cholinergic activity in comparison with noradrenergic activity is associated with depression or mania, respectively. Although the adrenergic–cholinergic balance hypothesis appears incomplete in the face of increasing data on the preeminent role of alterations in serotonergic, dopaminergic, and CRHergic neurotransmission in major depression, the importance of cholinergic mechanisms in some forms of depression is supported by both preclinical and clinical observations.

In certain animal models of depression (e.g., the forced-swim model), the administration of cholinesterase inhibitors such as physostigmine is "depressogenic" (McKinney 1984), whereas muscarinic receptor antagonists reverse the effects of such "procholinergic" agents. More convincing

evidence of the importance of acetylcholine in the maintenance of mood is the induction of depressed mood following administration of physostigmine or cholinergic agonists (e.g., arecoline) in euthymic control subjects (El-Yousef et al. 1973), unipolar depressed patients (Janowsky and Risch 1984), and bipolar manic patients (Janowsky and Risch 1984).

If cholinergic mechanisms contribute in some manner to the pathophysiology of major depression, then anticholinergic drugs should be effective antidepressants. Although physostigmine-induced dysphoria may be reversed with atropine (El-Yousef et al. 1973), there is no evidence that anticholinergic medications possess antidepressant properties (Janowsky and Risch 1984). Moreover, antidepressants, including the SSRIs, have little affinity for muscarinic cholinergic receptors yet are effective antidepressants. Sitaram et al. (1984) proposed that primary affective illness (specifically bipolar disorder) may be characterized by a state-independent cholinergic hypersensitivity in conjunction with a state-dependent noradrenergic supersensitivity (during late depression and early mania), which returns to normal during remission. They administered arecoline intravenously during the second non–rapid eye movement (NREM) sleep period of the night, which resulted in a more rapid onset of rapid eye movement (REM) sleep in currently depressed as well as remitted patients when compared with control subjects. This research group has replicated this finding of supersensitive cholinergic responses in patients with major depressive disorder (Dube et al. 1985; Jones et al. 1985). These findings also suggest that cholinergic sensitivity may play a key role in the pathogenesis of depression.

Brain-Derived Neurotrophic Factor

Brain-derived neurotrophic factor (BDNF) is a protein that plays a substantial role in the regulation of neuronal survival and the differentiation and function within the developing and adult CNS, and it also serves important regulatory roles in short- and long-term synaptic plasticity (Bramham 2007; Poo 2001). These effects appear to be mediated, in part, by the activity of the tyrosine kinase B receptor (TrkB, encoded by the *NTRK2* locus) on which BDNF acts. Functionally, BDNF appears to be important in episodic as well as emotion-related memory. Preclinical research using animal models of fear conditioning indicates a central role for BDNF and the TrkB receptor in the development of fear-related memory (Berton et al. 2006; Chhatwal et al. 2006; Rattiner et al. 2004, 2005). Clinical research with humans has identified a functional polymorphism within the BDNF gene that impacts hippocampal function and episodic memory (Egan et al. 2003).

The complex relationship that exists between stress and mood disorders may be mediated in part by the activity of BDNF and other neurotrophic factors (Table 45–14) (Duman and Monteggia 2006; Schmidt and Duman 2007) that ultimately may provide a window for the development of novel antidepressants (Berton and Nestler 2006), although discordant views have appeared (Groves 2007). In rodent models, stress has been found to decrease BDNF mRNA expression within the hippocampus using restraint (M. A. Smith et al. 1995a, 1995b), maternal deprivation (Roceri et al. 2002), and social defeat (Tsankova et al. 2006) paradigms, among others. Notably, reductions in the concentrations of other neurotrophic factors, including nerve growth factor (Ueyama et al. 1997), vascular endothelial growth factor (VEGF), and VEGF receptors (Heine et al. 2005), are also produced by stress as well. Postmortem studies of depressed suicide victims have demonstrated decreased hippocampal BDNF expression (Dwivedi et al. 2003; Karege et al. 2005). Increased hippocampal BDNF-like immunoreactivity in depressed patients treated with antidepressants (B. Chen et al. 2001) has been observed as well as downregulation of the extracellular regulated kinase (ERK) pathway, a major signaling pathway utilized by BDNF (Dwivedi et al. 2001, 2007) in completed suicides. Serum BDNF concentrations are decreased in depressed patients (Karege et al. 2002; Shimizu et al. 2003) and appear to normalize after antidepressant treatment (Aydemir et al. 2005; Gervasoni et al. 2005; Gonul et al. 2005).

TABLE 45–14. Alterations of the brain-derived neurotrophic factor system in depression

Postmortem studies of depressed suicide victims exhibit decreased hippocampal BDNF expression.
Increased hippocampal BDNF immunoreactivity is observed in depressed patients treated with antidepressants.
Downregulation of the extracellular regulated kinase pathway is seen in completed suicides.
Variety of antidepressant treatments used in humans increase the expression of hippocampal BDNF and block stress-induced downregulation of BDNF expression.

Note. BDNF = brain-derived neurotrophic factor.

The effects of stress appear to be regionally specific within the CNS. Restraint stress increases BDNF expression within the hypothalamus and pituitary (M. A. Smith et al. 1995a). An intriguing finding in regard to the relationship between stress, depression, and BDNF is that antidepressant treatments used in humans, including acute sleep disruption (Fujihara et al. 2003) as well as long-term administration of various antidepressants or repeated electroconvulsive treatments (Nibuya et al. 1995), increase the expression of hippocampal BDNF and block the downregulation of BDNF expression observed in response to restraint (Nibuya et al. 1995) or social defeat (Tsankova et al. 2006) stress paradigms or corticosterone treatment (Dwivedi et al. 2006). Experiments using BDNF knockout mice suggest that BDNF may also play a role in gender differences observed in depressive behavior and that the behavioral effects of antidepressants are at least partially dependent on BDNF (Monteggia et al. 2007).

One possible mediator of the effects of BDNF may be the cyclic adenosine monophosphate (cAMP) response element binding protein (CREB). Chronic, but not acute, administration of a variety of antidepressants, including 5-HT- and NE-selective reuptake inhibitors, increases the expression of hippocampal CREB mRNA in rats. In contrast, chronic administration of other psychotropic drugs does not lead to this effect, highlighting the pharmacological specificity of these effects (Nibuya et al. 1996). At the genomic level, one possible mechanism for the effects of antidepressants is chromatin modification by way of histone remodeling. Indeed, social defeat induces repressive BDNF promoter histone methylation, which is reversed by histone acetylation in the presence of chronic imipramine treatment (Tsankova et al. 2006).

NEUROIMAGING STUDIES

Frontal and Prefrontal Cortex

A number of studies using a variety of imaging modalities have identified functional abnormalities within the frontal and prefrontal cortex of patients with unipolar depression (Table 45–15) and bipolar disorder (Table 45–16). Compared with nondepressed individuals, patients with unipolar depression have a lateralized decrease in activity in the left lateral prefrontal cortex repeatedly documented by PET and single photon emission computed tomography (SPECT) investigations (Baxter et al. 1985, 1989; Bench et al. 1992; Dolan et al. 1992, 1993; Hurwitz et al. 1990; J. L. Martinot et al. 1990; Navarro et al. 2002), although this finding is apparently not specific to depression and has been seen in patients with schizophrenia (Barch et al. 2003; K. F. Berman et al. 1988; Dolan et al. 1993; Weinberger et al. 1986), depressed patients with Parkinson's disease (Ring et al. 1994) or traumatic brain injury (Jorge et al. 2004), and patients with other neurological diseases with depression as a secondary outcome (Mayberg 1994). Similarly, structural magnetic resonance imaging (MRI) studies have revealed prefrontal cortex abnormalities in unipolar depression, including reduced left subgenual prefrontal cortex volume (Botteron et al. 2002), increased lesion density in medial orbital prefrontal white matter (MacFall et al. 2001), and decreased medial orbitofrontal cortical volume (Ballmaier et al. 2004; Bremner et al. 2002; Lacerda et al. 2004; Monkul et al. 2007). Reductions in left prefrontal gray matter volume have also been reported in patients with bipolar disorder (Lopez-Larson et al. 2002).

TABLE 45–15. Abnormalities of the frontal and prefrontal cortex in unipolar depression by neuroimaging

Decreased activity within the left prefrontal cortex using both PET and SPECT methods that normalizes upon recovery from depression
Reduced left subgenual prefrontal cortex volume
Increased lesion density in medial orbital frontal white matter that correlates with depression severity in elderly depressed patients
Decreased medial orbitofrontal cortical volume in patients with remitted major depression

Note. PET = positron emission tomography; SPECT = single photon emission computed tomography.

TABLE 45–16. Abnormalities of the frontal and prefrontal cortex in bipolar disorder by neuroimaging

Reduced left prefrontal gray matter volume in patients with bipolar disorder
Depressed bipolar patients differentiated from depressed unipolar patients on subcortical and ventral prefrontal cortical responses to positive and negative emotional expression

Using patients with major depression, changes in prefrontal activity were initially associated with impaired cognition (Aizenstein et al. 2005; Bench et al. 1993; Okada et al. 2003). Metabolic changes observed in depressed patients normalize on recovery from depression, suggesting that the lateralized reduction in left prefrontal activity may be a state, rather than trait, marker for depression (Bench et al. 1995; Navarro et al. 2002; Schaefer et al. 2006). Since then, use of functional imaging of the prefrontal response in various visual imagery provocation paradigms has enabled the differentiation of depressed unipolar patients with and without anger attacks (Dougherty et al. 2004), anhedonic symptoms in unipolar patients (Keedwell et al. 2005a, 2005b), and response to valenced social imagery in unipolar depressed patients (Schaefer et al. 2006; Wang et al. 2006). Furthermore, depressed bipolar patients may be distinguished from depressed unipolar patients on the basis of subcortical and ventral prefrontal cortical responses to positive and negative emotional expressions (Lawrence et al. 2004). Additionally, imaging studies using nondepressed subjects have demonstrated a significant effect of genotype on the coupling of ventromedial prefrontal and amygdala activation following exposure to aversive imagery (Heinz et al. 2005). Consistent with the foregoing data, a recently reported stereotactic meta-analysis using pooled imaging data supports repeated findings of abnormal brain activation in depression within regions of the brain that represent the substrate for normal emotional experience in healthy subjects (Steele et al. 2007).

Subgenual Cingulate

The subgenual cingulate (Cg25) has received considerable attention in studies of patients with mood disorders (Table 45–17). Brain imaging studies (Brody et al. 2001; Drevets 1999; Mayberg 1994) suggested the importance of limbic–cortical pathways in the pathogenesis of major depression. Additional research (Mayberg et al. 1999; Seminowicz et al. 2004) demonstrated the importance of Cg25 in the modulation of acute sadness and response to antidepressant treatment, indicative of a role for Cg25 in the regulation of negative affect states. Cg25 possesses descending projections to a variety of brain regions (brain stem, hypothalamus, and insula) implicated in regulating neurovegetative and motivational states associated with depression (Barbas et al. 2003; Freedman et al. 2000; Jurgens and Muller-Preuss 1977; Ongur et al. 1998). Furthermore, a number of pathways link Cg25 to the orbitofrontal, medial prefrontal, and anterior and posterior cingulate cortices, providing a means through which autonomic and homeostatic processes influence learning, reward, and motivation (Barbas et al. 2003; Carmichael and Price 1996; Haber 2003; Vogt and Pandya 1987). Decreased activity of Cg25 has been associated with positive clinical response to a diverse variety of antidepressant treatments (Dougherty et al. 2003; Goldapple et al. 2004; Mayberg et al. 2000;

Mottaghy et al. 2002; Nobler et al. 2001). More recently, deep brain stimulation (DBS) of Cg25, originally developed for the treatment of Parkinson's disease (Benabid 2003), has been shown to produce significant clinical benefits for patients with treatment-resistant depression (Mayberg et al. 2005).

TABLE 45–17. Abnormalities of the subgenual cingulate in depression by neuroimaging

Neural activity in Cg25 correlates with experimental induction of acute sadness.
Decreased activity of Cg25 correlates with a positive clinical response to several different antidepressant treatments.
Deep brain stimulation of Cg25 produces clinical improvement in patients with treatment-resistant depression.

Note. Cg25 = subgenual cingulate.

Hippocampus

Owing to its major role in the regulation of both stress and learning, the hippocampus has been a major focus of neuroanatomical studies in patients with depression (Table 45–18). Functionally, the hippocampus plays a central role in adaptation to stress because of its seminal role in the regulation of HPA axis activity, as well as the registration of explicit memory and learning context. Furthermore, the hippocampus is a remarkably plastic structure, being a major site of neurogenesis in the adult brain while also possessing a well-demonstrated vulnerability to stress. Neurons of the CA3 region exhibit a loss of dendritic spines, reduced dendritic branching, and impaired neurogenesis in response to stress exposure (Duman and Monteggia 2006; Fuchs and Gould 2000; Nestler et al. 2002).

TABLE 45–18. Abnormalities of the hippocampus in depression by neuroimaging

Reduced hippocampal volume is found in some, but not all, patients with depression as well as those with other neuropsychiatric illnesses such as posttraumatic stress disorder.
In patients with hippocampal atrophy, the extent of atrophy correlates positively with the duration of depression.
Small hippocampal size may be a risk factor for depression.
Exposure to traumatic stress during childhood or adulthood is associated with decreased hippocampal volume.
Depression associated with childhood traumatic stress is associated with hippocampal atrophy, whereas depression without childhood traumatic stress is not.

Hippocampal vulnerability to stress may, in part, be a consequence of its high concentration of type I and type II corticosteroid receptors that enable the hippocampus to exert an inhibitory role on activity of the HPA axis (Jacobson and Sapolsky 1991). Prolonged exposure to high concentrations of corticosteroids during stress results in hippocampal damage in rodents (Magarinos and McEwen 1995a, 1995b; Magarinos et al. 1997) and nonhuman primates (Magarinos et al. 1996; Sapolsky et al. 1990; Uno et al. 1989, 1994). In humans, bilateral hippocampal atrophy has been observed in patients with Cushing's syndrome, in whom the extent of hippocampal atrophy correlates with the magnitude of corticosteroid hypersecretion (Starkman et al. 1992).

Reduced hippocampal size has been documented in a wide variety of neuropsychiatric disorders (Geuze et al. 2005). With respect to mood disorders, reduced hippocampal volume has been found in some (Bremner et al. 2000; Frodl et al. 2002b; Sheline 1996) but not all (Rusch et al. 2001; Vakili et al. 2000) studies of patients with unipolar depression (Campbell and Macqueen 2004). In patients with a history of depression who also have hippocampal atrophy, the extent of atrophy is greater in patients with a higher total lifetime duration of depression (Sheline et al. 1996, 1999). The finding of reduced hippocampal volume in patients with remitted unipolar depression (Neumeister et al. 2005) has raised the possibility that small hippocampal size may be a risk factor for depression.

Exposure to traumatic stress, either early in life or during adulthood, is associated with loss of hippocampal volume and has been documented in individuals with combat-induced (Bremner et al. 1995; Vythilingam et al. 2005), childhood abuse–related (Bremner et al. 1997b, 2003), and chronic (Kitayama et al. 2005) PTSD as well as those with dissociative identity disorder (Vermetten et al. 2006). Similarly, patients with a history of early-life stress or trauma and depression also have been found to have decreased hippocampal volume (Driessen et al. 2000; Stein et al. 1997). Vythilingam et al. (2002) reported that depressed women with a history of childhood sexual abuse, but not depressed women without such a history, had a reduction in hippocampal volume compared with control subjects, suggesting that previous reports of reduced hippocampal size in patients with depression may in fact be secondary to childhood trauma rather than to depression per se.

Basal Ganglia

Vulnerability to affective dysfunction might derive from disruption of connections between the basal ganglia or from interruption of pathways connecting the basal ganglia to other parts of the brain, specifically the limbic system and prefrontal cortex (Alexander et al. 1986; K. R. Krishnan 1991). A substantial preclinical literature suggests a major role for the nucleus accumbens/ventral striatum and ventral tegmental area in the motivational and hedonic components of mood disorders (Nestler and Carlezon 2006).

Initial imaging investigations into the role of the basal ganglia focused on metabolic and volumetric comparisons between different populations of mood disorder patients and healthy control subjects. These studies have used a variety of imaging modalities and have identified structural and functional abnormalities within components of the basal ganglia of patients with unipolar depression (Table 45–19) and bipolar disorder (Table 45–20). For example, a PET study measuring neural activity of different brain regions of manic and euthymic patients with bipolar disorder showed increased activity in the head of the left caudate as well as in the left dorsal anterior cingulate among subjects with symptoms of mania (Blumberg et al. 2000). PET and functional magnetic resonance imaging (fMRI) studies of patients with major depression found that left caudate activity was lower in depressed patients with psychomotor retardation compared with depressed patients with anxiety and healthy control subjects (M. Martinot et al. 2001). In a structural MRI study of patients with bipolar disorder compared with matched healthy control subjects, the age of the patients and length of illness correlated with respectively larger left globus pallidus and smaller left putamen volumes (Brambilla et al. 2001).

TABLE 45–19. Abnormalities of the basal ganglia in unipolar depression by neuroimaging
Decreased left caudate activity in depressed patients with psychomotor retardation compared with depressed patients with anxiety and healthy control subjects
Behavioral response to feedback associated with abnormal activity within the medial caudate and ventromedial orbitofrontal cortex
Correlation between psychomotor–anhedonia symptoms and decreased activity of the anteroventral caudate and putamen during nonemotional auditory task
Reduced activation of the right putamen in response to facial expressions of increasing happiness
Reduced bilateral ventral striatal activation in response to positive stimuli that correlates with the extent of anhedonia in depressed patients

TABLE 45–20. Abnormalities of the basal ganglia in bipolar disorder by neuroimaging
Increased activity of the head of the left caudate and the left dorsal anterior cingulate in manic patients using positron emission tomography methods

Increased volume of the left globus pallidus and decreased volume of the left putamen correlates with the age of bipolar patients and the length of illness

Increased subcortical and ventral prefrontal cortical response to positive and negative emotional expressions

Increased metabolic activity in the caudate and ventral striatum of medicated depressed bipolar II patients

Several imaging studies are consistent with deficient responsiveness of frontostriatal circuits of depressed patients. Elliott et al. (1998) reported that the behavioral response to feedback in depressed patients is associated with an abnormal neural response within the medial caudate and ventromedial orbitofrontal cortex. Building on this finding, other investigators (Dunn et al. 2002) reported a correlation between the psychomotor–anhedonia symptom cluster of the Beck Depression Inventory and decreased metabolism within the anteroventral caudate and putamen in subjects performing a nonemotional auditory task. Depressed patients have also been found to exhibit reduced activation of the right putamen in response to facial expressions of increasing happiness (Surguladze et al. 2005). Furthermore, in comparison with healthy control subjects and unipolar depressed patients, bipolar patients demonstrate increased subcortical and ventral prefrontal cortical responses to both positive and negative emotional expressions (Lawrence et al. 2004). Epstein et al. (2006) used a functional imaging paradigm to examine the ventral striatal responses to positive and negative stimuli in depressed patients. Depressed subjects exhibited reduced bilateral ventral striatal activation in response to positive stimuli, and this decrease was correlated with reduced interest/pleasure in, and performance of, activities. More recently, increased metabolic activity has been reported in the caudate and ventral striatum of medicated depressed bipolar II patients (Mah et al. 2007).

Amygdala

The amygdala is known to play a significant role in the processing of emotions and affectively charged stimuli (Davidson et al. 2002). For example, Isenberg et al. (1999) found significantly greater bilateral amygdala activation during both the response to and the perception of emotionally charged stimuli when compared with non–emotionally charged stimuli. Several imaging studies of patients with mood disorders have focused on elucidating the association between mood alterations and abnormalities in the amygdala (Table 45–21) as well as other structures (Leppanen 2006; Phan et al. 2004). An initial report found that increased resting metabolism within the right amygdala of depressed patients is predictive of negative affect (Abercrombie et al. 1998). Subsequent fMRI investigation using a masked face paradigm found relative increased activity of the left amygdala among depressed patients that normalized with antidepressant treatment (Sheline et al. 2001). Similarly, increased activation of the left amygdala in depressed adolescents using evocative face viewing has been associated with poor memory for faces relative to healthy and anxious control subjects (Roberson-Nay et al. 2006). In addition to the response to valenced visual stimuli, the amygdala also responds differentially to both positive and negative words (Hamann and Mao 2002). Using PET methodologies, Drevets et al. (2002) reported that left amygdala metabolism was increased and positively correlated with stress-induced plasma cortisol concentrations in subjects with unipolar and bipolar depression.

TABLE 45–21. Abnormalities of the amygdala in unipolar depression and bipolar disorder by neuroimaging

Increased activity of left amygdala during evocative face viewing and normalization with antidepressant treatment in unipolar depressed patients

Increased activity of left amygdala positively correlated with stress-induced plasma cortisol in unipolar and bipolar depressed patients

Bilateral increases in amygdala volume in first-episode, but not recurrent, major depression

In depression, sustained amygdala processing in response to negative information possibly correlated with self-reported rumination

Anticipation of aversive stimuli increases activation of the extended amygdala in women with major depression

Decreased density of amygdala serotonin transporter (5-HTT) in unipolar and bipolar depressed patients

Structural imaging studies have identified bilateral increases in amygdala volume in patients during the first episode of major depression (Frodl et al. 2002a; Lange and Irle 2004), although not in patients with recurrent depression (Frodl et al. 2003). Increased right amygdala volume has been reported in women with depression and a history of suicidality (Monkul et al. 2007). Decreased amygdala volume (Rosso et al. 2005) and blunted amygdala activation have been reported in children with depression (Thomas et al. 2001). Sustained activation of the amygdala observed in unipolar depressed patients relative to nondepressed control subjects in response to negative information correlates with self-reported rumination (Siegle et al. 2002), as well as personal relevance rating of words (Siegle et al. 2007). Anticipation of aversive stimuli increases activation of the extended amygdala in women with major depression compared with healthy control subjects (Abler et al. 2007).

Serotonin may play a central role in modulating amygdala activity during emotional information processing (Hariri and Holmes 2006). Genomic imaging studies using nondepressed subjects have demonstrated a significant effect of 5-HTT genotype on the response of the amygdala to fearful stimuli (Hariri et al. 2002); the coupling of ventromedial prefrontal, cingulate, and amygdala activation (Heinz et al. 2005; Pezawas et al. 2005); and the response to tryptophan depletion in patients with remitted depression (Neumeister et al. 2006). Short-term administration of the SSRI citalopram to nondepressed subjects alters amygdala reactivity to nonconscious threat stimuli (Harmer et al. 2006), and amygdala reactivity may be influenced partially by the density of amygdala 5-HT_{1A} receptors (Fisher et al. 2006). Depressed patients, both bipolar and unipolar, have decreased 5-HTT density within the amygdala (Oquendo et al. 2007).

Thalamus

It is unclear whether thalamic volumes are altered in patients with mood disorders (Table 45–22). A structural imaging study comparing patients with bipolar disorder, patients with unipolar depression, and healthy control subjects found no differences between groups with respect to thalamic volume (Caetano et al. 2001). Consistent with this finding, several previous studies also failed to show differences in thalamic volumes of patients with mood disorders compared with healthy control subjects (Buchsbaum et al. 1997; K. R. Krishnan et al. 1993; Strakowski et al. 1993). Alternatively, other studies have found smaller thalamic volumes in patients with bipolar disorder and unipolar depression (Dasari et al. 1999; Dupont et al. 1995). Interestingly, in a PET study, decreased glucose metabolism in the thalamus was reported in patients with unipolar depression (Buchsbaum et al. 1997).

TABLE 45–22. Abnormalities of the thalamus in unipolar depression and bipolar disorder by neuroimaging

The relation between thalamic abnormalities and mood disorders remains unclear.

Smaller thalamic volumes may be associated with bipolar disorder and unipolar depression.

Decreased metabolism in the thalamus may be associated with unipolar depression.

Pituitary

Relatively few imaging studies have measured pituitary volumes in patients with mood disorders (Table 45–23). Pituitary volumes were reported to be larger in patients with major depression (16

with unipolar depression and 3 with bipolar depression) in comparison with healthy control subjects (K. R. Krishnan et al. 1991). In a study of psychiatric inpatients, of whom 20 had unipolar depression, a positive correlation was found between postdexamethasone plasma cortisol concentrations and pituitary volume (Axelson et al. 1992). In contrast, in a study examining the association between seasonal depression and pituitary volumes, no significant difference in pituitary volumes was found between acutely depressed patients and healthy control subjects (Schwartz et al. 1997). In a study of patients with bipolar disorder, patients with unipolar depression, and healthy control subjects, no differences in pituitary volumes were observed between patients with unipolar depression and control subjects; however, significantly smaller pituitary volumes were found in the patients with bipolar disorder (Sassi et al. 2001). In a more recent study, pituitary volumes did not differ between pediatric bipolar patients and control subjects (H. H. Chen et al. 2004).

TABLE 45–23. Abnormalities of the pituitary in unipolar depression and bipolar disorder by neuroimaging

Pituitary volumes may be increased in patients with bipolar and unipolar depression.

Postdexamethasone plasma cortisol concentrations appear to be positively correlated with pituitary volumes among unipolar depressed patients.

No significant correlation has been found between seasonal depression and pituitary volumes.

Few studies have examined the relation between pituitary volume and mood disorders.

INFLAMMATION, DEPRESSION, AND STRESS

A growing body of evidence suggests that systemic inflammation may contribute to the pathophysiology of mood disorders (Table 45–24). Inflammation is a key component of the adaptive response to stress (Chrousos 1995). Acute stress results in secretion of proinflammatory cytokines (Elenkov et al. 2005; Glaser and Kiecolt-Glaser 2005; McEwen 1998), peripheral secretion of acute-phase proteins such as fibrinogen and C reactive protein that promote infection resistance and tissue repair, and induction of nuclear factor kappa B (NF-κB), a candidate mediator for some of the CNS effects related to the inflammatory response (Bierhaus et al. 2003). The latter is also a potentially important mediator in synaptic development within the central and peripheral nervous systems (Gutierrez et al. 2005). Another component of the adaptive response to acute stress is increased HPA axis activity and its end product, the increased secretion of glucocorticoids, that act on intracellular signaling pathways that help to terminate the inflammatory response after cessation of acute stress (Chrousos 1995). This relationship between the HPA axis and systemic inflammation may be especially relevant to mood disorders in view of the findings that patients with a history of early-life stress have an impaired capacity to regulate the HPA axis in the presence of psychosocial stress (Heim et al. 2000) as well as an increase in inflammatory cytokines, suggesting that control of the inflammatory response may be impaired as well.

TABLE 45–24. Inflammation and depression

Systemic inflammation may play a key role in the etiology of a number of common medical diseases, including diabetes, cardiovascular disease, and depression.

Nuclear factor kappa B is a candidate mediator for some of the CNS effects related to the inflammatory response.

Administration of proinflammatory cytokines to laboratory animals results in behavioral and neurovegetative symptoms that are similar to those observed in patients with depression.

Clinical research in humans has identified a number of proinflammatory cytokines that are elevated in patients with depression.

Humans treated with interferon-α, which promotes the release of IL-6, IL-1β, and TNF-α, commonly develop symptoms of depression.

Patients with a history of childhood trauma have an elevated risk not only for depression but also for a variety of common chronic medical diseases.

A graded relationship exists between childhood maltreatment and elevations in plasma inflammatory markers in adulthood.

Depressed male patients with a history of early-life stress demonstrate an increased inflammatory response to acute psychosocial stress.

Note. CNS = central nervous system; IL = interleukin; TNF-α = tumor necrosis factor–alpha.

A diverse and growing database indicates that systemic inflammation may play a key role in the etiology of a number of common medical diseases including diabetes (Wellen and Hotamisligil 2005), cardiovascular disease (Willerson and Ridker 2004), cancer (Li et al. 2005), and depression (Evans et al. 2005; Maes 1999; Raison et al. 2006) (see Table 45–24). Administration of proinflammatory cytokines to laboratory animals results in a pattern of behavioral and neurovegetative symptoms known as "sickness behavior" that is similar to the depression observed in human patients and includes psychomotor slowing, fatigue, elevated pain sensitivity, disrupted sleep, and anxiety (Kent et al. 1992). Clinical research in humans has identified an array of proinflammatory cytokines including interleukin (IL)-6, IL-1β, and tumor necrosis factor–alpha (TNF-α) (Alesci et al. 2005; Kahl et al. 2005; Miller et al. 2002; Musselman et al. 2001b; Penninx et al. 2003) and inflammatory markers such as C reactive protein (Danner et al. 2003; Ford and Erlinger 2004; Kahl et al. 2005; Miller et al. 2002; Panagiotakos et al. 2004; Penninx et al. 2003) that are elevated in patients with depression. Humans treated with interferon-α, which promotes the release of IL-6, IL-1β, and TNF-α, commonly develop symptoms of depression, and a significant subset of these individuals fulfill diagnostic criteria for an episode of major depression (Musselman et al. 2001a; Raison et al. 2005), which may be effectively treated with SSRIs (Musselman et al. 2001a).

Inflammation may be particularly relevant to three populations of depressed patients: those with treatment-resistant depression (Maes 1999; Sluzewska et al. 1997), those with chronic medical illness comorbid with depression (Evans et al. 2005), and those with depression associated with early-life stress (Danese et al. 2007; Pace et al. 2006). In some patients, exposure to trauma or stressful childhood experiences may be a variable connecting risk for depression, chronic medical illness, and inflammation. Thus, patients with childhood trauma have an elevated risk not only for depression (Kendler et al. 2004), which is often chronic in course (Hayden and Klein 2001; Kaplan and Klinetob 2000; Lara et al. 2000), but also for a variety of common, chronic, and progressive medical diseases including coronary artery disease (R. D. Goodwin and Stein 2004). Elevated levels of inflammatory markers including C reactive protein, fibrinogen, and IL-6 are associated with psychosocial risk factors for cardiovascular disease (Ranjit et al. 2007), and a graded relationship exists between childhood maltreatment and elevations in plasma C reactive protein concentrations in adulthood (Danese et al. 2007). Moreover, depressed male patients with a history of early-life stress demonstrate an increased inflammatory response to acute psychosocial stress (Pace et al. 2006).

GENETIC STUDIES OF MOOD DISORDERS

Major depressive disorder and bipolar disorder are both, in part, heritable illnesses (Table 45–25). Heritability estimates for major depression based on estimates from twin studies range from 40% to 50% with respect to major depressive disorder (Bierut et al. 1999; Kendler et al. 1993, 2001a; McGuffin et al. 1991, 1996; P. F. Sullivan et al. 2000; Torgersen 1986) and as high as 85% to 93% for bipolar disorder (Kieseppa et al. 2004; McGuffin et al. 2003). Genetic influences on resilience to depression may be as important as the genetic influence on vulnerability to depression (Rijsdijk et al. 2003). Adoption studies also support the notion of a substantial genetic component of risk for major

depression (Cadoret 1978; Mendlewicz and Rainer 1977; Wender et al. 1986) and bipolar disorder (Wender et al. 1986). Family studies indicate that the relative risk ratio for major depression probands is 2%–3% (Gershon et al. 1982; Maier et al. 1992; Weissman et al. 1984), whereas risk for the development of bipolar disorder among first-degree relatives of bipolar probands ranges from 5% to 12% (Alda 1997). When the scope of risk is expanded to include the development of any form of mood disorder, risk for first-degree relatives of bipolar probands increases to 20% to 25% (Smoller and Finn 2003). Finally, risk for the development of major mood disorder (unipolar or bipolar) is increased by exposure to detrimental environmental factors such as childhood abuse and neglect or other forms of early-life stress that promote vulnerability to major depression (Kendler et al. 2002, 2004) and bipolar disorder (Neria et al. 2005).

TABLE 45–25. Genetics and mood disorders

Family, twin, linkage, and association studies support a strong role for genetic liability with respect to risk for depression.

Mood disorders are complex (as opposed to Mendelian or single-gene) genetic diseases involving multiple and variably penetrant genes with individually variable modes of inheritance.

Interactions between individual genes and the environment are likely to play an important role in the etiology of unipolar depression and bipolar disorder.

Genetic influences on both resilience and risk for the development of mood disorders are developing areas of investigation in psychiatric genetics.

The mode of inheritance for major depression (Marazita et al. 1997; Moldin et al. 1991; Price et al. 1987) and bipolar disorder (Nurnberger and Foroud 2000) is unclear. Historically, genetic research on mood disorders has focused on the use of single gene models that likely do not apply to major depression, bipolar disorder, or other psychiatric illnesses. Like many common medical illnesses such as hypertension, coronary artery disease, and diabetes mellitus, mood disorders as clinical syndromes likely evolve from the differential contribution of multiple variably penetrant genes with differing modes of inheritance and whose expression is likely influenced by environmental exposures and possibly architectural changes within the genome such as genomic rearrangement or copy number variation. As a consequence, major depression, types I and II bipolar disorder, and other forms of mood disorder such as minor depression, dysthymia, and cyclothymia may be termed *complex* genetic diseases (Baron 2001; Jaffee and Price 2007; Lee and Lupski 2006; N. J. Risch 2000). The term *complex* stands in distinction to classic genetic diseases such as Huntington's disease or phenylketonuria, often referred to as Mendelian disorders (in honor of the Augustinian monk Gregor Mendel), in which mutations of a single gene are entirely or largely responsible for a particular disease. Within the context of complex genetic disease, additive and multiplicative, rather than purely dominant or recessive, models of genetic risk may be useful in dissecting the genetic contribution to major depression and bipolar disorder (Orstavik et al. 2007; Rijsdijk et al. 2003) as well as other forms of psychiatric disease (Comings 2001).

Candidate Gene Studies

An enormous body of research examining candidate genes for mood disorders and other psychiatric illnesses exists. Much of this research has focused on attempting to identify candidate genes whose allelic variants are thought to predict differences in risk for categorical diagnosis of major depression or quantitative differences in depressive symptomatology either alone, as genetic main effects, or in concert with the environment. In some cases, these variants are single nucleotide polymorphisms (SNPs) that alter the regulation of the gene or the structure of the protein that it codes for, whereas in other cases the gene variants may be structural alterations within the genome such as variable number tandem repeats (VNTRs) that alter the function of the gene they reside within, or the investigated variants may themselves just be markers of so far unknown genetic variation close by.

Some of the more well-known genes that have been investigated include the 5-HTT gene (Caspi et al. 2003; Chorbov et al. 2007; Kaufman et al. 2006; Kendler et al. 2005), the BDNF gene (Kaufman et al. 2006), the glucocorticoid receptor chaperone protein gene *FKBP5* (Binder et al. 2004; Lekman et al. 2008; Willour et al. 2008), and the type 1 corticotropin-releasing hormone receptor gene (Bradley et al. 2008; Licinio et al. 2004).

The candidate gene literature for psychiatric disease is complex, and the frequently discordant results between well-designed studies of candidate genes make interpretation of the literature challenging (Caspi et al. 2003; Chorbov et al. 2007). Comprehensive review of this literature is beyond the scope of this chapter (but see Craddock and Forty 2006; Kato 2007; Levinson 2006 for useful reviews). Some continuing areas of intense discussion include the phenotypic description of psychiatric disease (Bearden et al. 2004; Craddock and Forty 2006) and putatively related endophenotypes (Bearden and Freimer 2006; Cannon and Keller 2006; Hasler et al. 2004), measurement of gene–environment interactions and correlations (Craddock and Forty 2006; Eaves 2006; Jaffee and Price 2007), epigenetic influences on the genome (Mill and Petronis 2007), statistical issues related to multiple comparisons (Abecasis et al. 2005; Sabatti et al. 2003), and study replication criteria (Chanock et al. 2007).

Association studies investigating individual candidate genes differ fundamentally from linkage studies in that they generate a hypothesis that a particular gene, or region of a gene, plays a central role in some component of the pathophysiology of a disease. Historically, candidate genes for association studies have been chosen on the basis of linkage data or a biological rationale for how a particular gene may contribute to the production, maintenance, or relapse of the disease under investigation. We provide a brief selected review of candidate gene studies in mood disorders below.

Serotonin

The 5-HTT gene, *SLC6A4* (Lesch et al. 1993), has repeatedly been implicated as an important candidate gene in association studies conducted with depressed patients. Several polymorphisms have been described for this gene. A common functional polymorphism in the 5' promoter region of *SLC6A4,* referred to as the 5-HTT gene–linked polymorphic region (5-HTTLPR), consists of a repetitive region containing 16 imperfect repeat units of 22 bp, located ~1,000 bp upstream of the transcriptional start site (Heils et al. 1996; Lesch and Mossner 1998) (for more detail, see Chapter 3 in this volume, "Genetics and Genomics"). The 5-HTTLPR has been associated with different basal activity of the transporter, most likely related to differential transcriptional activity (Gelernter et al. 1999). The long variant (L allele) of this polymorphism has been shown to lead to higher serotonin reuptake by the transporter in vitro. However, a PET study could not identify differences in serotonin transporter binding potential by 5-HTTLPR genotype in healthy control subjects or patients with major depression (Parsey et al. 2006). Other potentially functional polymorphisms include a VNTR polymorphism located within intron 3 as well as several nonsynonymous SNPs in the coding region (for a review, see Hahn and Blakely 2002). The latter polymorphisms have been less studied in psychiatric genetics, while for the 5-HTTLPR, well over 400 association studies are listed in PubMed to date. The effects of this polymorphism on response to SSRI treatment have been investigated by a number of studies, and a recent meta-analysis by Serretti et al. (2007) indicates that the L allele may be associated with a beneficial response profile. However, this finding could not be replicated in the large Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial, and some evidence suggests that this association with treatment response may be carried by an increased risk for side effects in individuals carrying the short variant (S allele) (Kraft et al. 2007; Murphy et al. 2004).

A large number of studies have investigated the association of this polymorphism with unipolar and bipolar depression as well as suicide. Several meta-analyses on this topic seem to support an involvement of this polymorphism in bipolar disorder and suicide attempts, albeit with odds ratios less than 1.2 for bipolar disorder (Anguelova et al. 2003; Cho et al. 2005; Lasky-Su et al. 2005; Li and He

2007; Lin and Tsai 2004; Lotrich and Pollock 2004). Associations with unipolar depression are more controversial and are likely dependent on gene–environment interactions that are now well validated for this polymorphism. Using a large well-characterized cohort in New Zealand, Caspi et al. (2003) demonstrated that exposure to stress in childhood, in concert with a particular 5-HTTLPR genotype, predicts depressive symptoms in adulthood. This finding has now been replicated in a series of studies (Eley et al. 2004; Grabe et al. 2005; Kaufman et al. 2004; Sjoberg et al. 2006; Wilhelm et al. 2006). Twin-study replications (Kendler et al. 2005) and nonreplications (Gillespie et al. 2005) of this finding have also been reported, as have been findings in twins that are discordant with respect to the genotype of risk (Chorbov et al. 2007) but concordant with respect to an effect of stress and genotype on depressive symptomatology. The gene–environment interactions with this polymorphism have been the first well-established interactions of this kind in the genetics of mood disorders.

HPA Axis–Related Genes

As described in the previous section, a large and diverse body of evidence indicates a substantial role for HPA axis dysregulation in depression. Licinio et al. (2004) identified a unique haplotype within the *CRHR1* gene, which codes for the CRH_1 receptor, that predicts antidepressant response in Mexican Americans, and this has been replicated in a Chinese sample (Liu et al. 2007). Furthermore, associations with major depression have also been reported for this gene (Liu et al. 2006).

More recently, Bradley et al. (2008) reported data, ascertained from a large sample of heavily traumatized inner-city African Americans, identifying SNPs as well as haplotypes within the *CRHR1* gene that predict scores on the Beck Depression Inventory as a function of trauma exposure. Interestingly, gene–environment interactions of this gene with lifetime stress have also been reported for suicide attempts in males (Wasserman et al. 2008). SNPs of the *FKBP5* gene, which codes for a co-chaperone of the glucocorticoid receptor, also have been reported to predict antidepressant response and the response to the dexamethasone–CRH stimulation test by Binder et al. (2004) in two independent European samples, and this was replicated in the STAR*D sample (Lekman et al. 2008). Interestingly, while the results for association with unipolar depression are controversial (Binder—negative, Lekman—positive), a recently published family study shows evidence for association of *FKBP5* with bipolar disorder (Willour et al. 2008), and a recently published association study provides evidence that *FKBP5* SNPs interact with severity of child abuse to predict PTSD symptoms in adults (Binder et al. 2008).

Brain-Derived Neurotrophic Factor

As described earlier in the chapter, BDNF may play a key role in synaptic maintenance and neurotransmission and thus participate in the biology of mood disorders. More recently, the BDNF Val66Met polymorphism has also emerged as a factor moderating risk for stress-sensitive diseases such as diabetes mellitus (Krabbe et al. 2007) and systemic lupus erythematosus (Oroszi et al. 2006).

Strauss et al. (2004, 2005) as well as others (Geller et al. 2004) have identified an association between BDNF genotype and childhood-onset mood disorder. Similar studies examining associations between polymorphisms of the BDNF receptor TrkB (*NTRK2*) and childhood-onset mood disorder have been negative (Adams et al. 2005). Examining children for risk of depression in a more elaborate study, Kaufman et al. (2006) reported data suggesting that particular variants of the 5-HTT gene and the Met allele of the BDNF Val66Met polymorphism in the context of early-life stress influence the development of depression in children. Notably, these variants only confer risk for depression in the presence of a history of childhood maltreatment, and positive experiences in childhood offset this risk. Similar findings, with respect to the effects of stressful life events on risk for depression as a function of 5-HTT and Val66Met genotype, have been reported in a sample of geriatric Korean patients (J. M. Kim et al. 2007). Other investigators have reported associations between the Val66Met polymorphism and risk for major depression (L. Ribeiro et al. 2007; Schumacher et al. 2005). Alternatively, other

reports (Iga et al. 2007) indicate an association between Val66Met genotype and psychosis or suicidal behavior, but not major depression, in a Japanese population.

In addition to studies indicating risk for depression in the setting of early-life stress with respect to BDNF Val66Met genotype, other investigators have examined the relationship between BDNF and bipolar disorder. Several groups (Geller et al. 2004; Neves-Pereira et al. 2002; Sklar et al. 2002) report positive associations between BDNF genotype and bipolar disorder, although discordant results exist (Green et al. 2006; Oswald et al. 2004). More recently, a meta-analysis of pooled data was unable to provide evidence to support an association between the Val66Met polymorphism and bipolar disorder (Kanazawa et al. 2007).

One way that variability within BDNF may influence the development of depression is regulation of the reactivity of the HPA axis. Preliminary data exist indicating that homozygous carriers of the Met/Met genotype demonstrate significantly higher HPA axis activity during the DEX/CRH test than patients carrying the Val/Val or Val/Met genotype (ACTH, cortisol) (Schule et al. 2006). Consistent with this is a recent report that smaller hippocampal volumes were observed for depressed patients and for control subjects carrying the Met BDNF allele compared with subjects homozygous for the Val BDNF allele (Frodl et al. 2007).

Whole-Genome Association Studies

The recent introduction of technological platforms for whole-genome association (WGA) studies provides an opportunity to rapidly identify allelic variants of novel candidate genes for further investigation without theoretical bias (for a review, see Chapter 3 in this volume, "Genetics and Genomics"). Within the literature of psychiatric genetics, WGA studies have begun to appear, and at present there are reports for Alzheimer's disease (Coon et al. 2007), schizophrenia (Lencz et al. 2007), and bipolar disorder (Baum et al. 2008; Wellcome Trust Case–Control Consortium 2007). Candidate gene studies to evaluate the initial findings from these reports are currently under way.

CONCLUSION

In this chapter we have provided an overview of research findings on the biology of mood disorders. However, the central question of what variables drive the pathophysiology of mood disorders remains unanswered. Since the last edition of this textbook, research examining the role of developmental stress, trauma, and genetic risk in the etiology of mood disorders has grown considerably. These findings have enriched our understanding of the biological relationships between environmental and genetic risks for mood disorders. Interpretation of seemingly disparate findings from the continuously growing number of individual biological studies is challenging, but over time, integration of these findings will form an overarching understanding of these complex disorders.

Chapter 46. Neurobiology of Schizophrenia

NEUROBIOLOGY OF SCHIZOPHRENIA: INTRODUCTION

Schizophrenia is a complex disorder defined by positive symptoms (hallucinations, delusions, thought disorder), negative symptoms (apathy, alogia, anhedonia, blunted affect), and deterioration of the patient's personal, social, and occupational functioning. Recent advances in elucidating the neurobiology of schizophrenia have capitalized on progress in clinical and basic neuroscience that has contributed to the integration of neurobiology with the clinical features of the disorder.

In this chapter, we highlight selected areas emphasizing recent progress and short-term future goals. Noteworthy advances link clinical and basic neuroscience research, address mechanisms underlying this challenging disorder, and have implications for treatment. Such progress includes strong evidence of selective cognitive deficits against a background of global impairment, aberrations in electrophysiological activity in response to sensory input, and abnormalities in brain anatomy and physiology through the application of structural and functional neuroimaging methods; a shift from examining the genetics of diagnostic categories to a focus on endophenotypic markers with parallel paradigms in humans and animals; identification of specific candidate genes from genomewide scans and microarray technologies; evidence of cellular and molecular abnormalities in diverse brain regions; and a growing appreciation of schizophrenia as a life span neurodevelopmental disorder. Considered jointly, these advances establish a firm foundation for hypothesis-driven research that systematically examines core neurobiological abnormalities underlying schizophrenia.

When evaluating the body of data on the neurobiology of schizophrenia, two important questions deserve further consideration.

First, are the findings specific to schizophrenia? That is, are the brain abnormalities observed on multiple levels of analysis unique to schizophrenia, or do they characterize psychosis? Although the literature across the methods we summarize is limited regarding direct prospective comparisons between patients with schizophrenia and patients with bipolar disorder, overall it appears that patients with schizophrenia are distinct from those with bipolar disorder. Thus, despite commonality in some underlying affected brain systems, the extent and topography of aberrations observed differentiate schizophrenia from bipolar disorder.

Second, do the abnormalities observed relate to clinical subtypes as defined by DSM-IV-TR (American Psychiatric Association 2000) or to symptom dimensions such as positive and negative symptoms of schizophrenia? The literature, in general, suggests "a signature" across subtypes of schizophrenia and symptom dimensions, with some variability related to illness duration and severity. We are now at the cusp of advancing the understanding of brain circuitry that examines neurocognitive and affective processes that relate to social cognition in schizophrenia. As progress is made, it can guide novel therapeutics that target these deficits more directly.

NEUROBEHAVIORAL DEFICITS

Impaired cognition in schizophrenia, leading to early conceptualizations of "dementia praecox" (Kraepelin 1919), is well recognized and fundamental to the disorder. While the clinical symptoms and course of the disorder are heterogeneous, most patients with schizophrenia exhibit cognitive deficits

that are present at the onset of illness and persist following improvement in their psychosis. Neuropsychological studies have found impairments in multiple domains, including perception, attention, visuospatial abilities, language, memory, emotion, executive function, and coordination (Sharma and Harvey 1999). However, within this diffuse impairment, attention, working and episodic memory, and executive functioning are more severely impaired (Cornblatt and Keilp 1994; Heinrichs and Zakzanis 1998; Saykin et al. 1994). While neurocognitive measures have shown limited, albeit consistent, relation to clinical symptoms, they appear more closely related to functional outcome (Goldberg and Gold 1995; Green 1996; Green et al. 2000).

In addition to the relevance of neuropsychological measures to functioning and outcome, they have stimulated the investigation of their underlying neurobiology. Several brain systems are implicated by these deficits. The attention-processing circuitry includes brain stem–thalamo-striato-accumbens-temporal-hippocampal-prefrontal-parietal regions. Deficits in working memory implicate the dorsolateral prefrontal cortex, and the ventromedial temporal lobe is implicated in deficits in episodic memory. A dorsolateral-medial-orbital prefrontal cortical circuit mediates executive functions.

Relative to the extensive and well-documented cognitive deficits in schizophrenia, more recently, emotion-processing and olfaction deficits have also been noted. Clinically, emotional impairment is manifested in flat, blunted, inappropriate affect and in depression (Gur et al. 2006; Kohler et al. 2000b). Although these clinical features have been detailed as part of the disorder, the methodologies for neuroscience research have lagged behind research on cognition. Studies have reported emotion-processing deficits in identification, discrimination, and recognition of facial expressions (Kring and Neale 1996). Although these deficits may represent generalized cognitive impairment (Kerr and Neale 1993), they relate specifically to symptoms and neurobiological measures (Kohler et al. 2000a). Animal and human investigations have implicated the limbic system, primarily the amygdala, hypothalamus, and mesocorticolimbic dopaminergic systems, and cortical regions including orbitofrontal, dorsolateral prefrontal, temporal, and parts of the parietal cortex (LeDoux 2000).

Psychophysical studies of schizophrenia have described impairments in elementary sensory perceptual processing. Patients are impaired in their ability to detect and identify odors (Moberg et al. 1999). Olfactory deficits are present at the onset of illness, do not relate to disease severity or treatment, and are possibly progressive (Kopala et al. 1993). It is unclear whether the deficits are part of the generalized neurocognitive impairment (Moberg et al. 2006). The neuroanatomical differences noted in patients (Turetsky et al. 2000) suggest that olfactory bulb changes and medial temporal lobe abnormalities could mediate the observed behavioral aberrations. In the visual domain, abnormalities in elementary contrast sensitivity and functional dyslexia have been described (Butler and Javitt 2005; Kurylo et al. 2007; Revheim et al. 2006), and electrophysiological studies have suggested dysfunction of the thalamic lateral geniculate's magnocellular processing stream as playing a role in these deficits. In the auditory domain, deficits in tone discrimination and matching have been reported (Javitt et al. 2000), consistent with many electrophysiological studies and recent postmortem evidence of primary auditory cortex abnormality in schizophrenia (Sweet et al. 2007).

The application of neurobehavioral probes (Gur et al. 1992) in functional imaging studies has helped elucidate links between neurobehavioral deficits and the underlying brain dysfunction evident in schizophrenia. With these paradigms, we can examine the topography of brain activity in response to engagement in tasks in which deficits have been noted in patients. This provides "on-line" correlation between brain activity and performance in a way that permits direct examination of brain–behavior relations.

ELECTROPHYSIOLOGY

Event-related potentials (ERPs), coupled with specific stimulus events and cognitive tasks, enable monitoring of associated brain activity in real time. There is an extensive literature on ERP

abnormalities in schizophrenia (Adler et al. 1982; Erwin et al. 1991; Grillon et al. 1991) including deficits in early preattentive stages of information processing and relatively late higher cortical processes. Aberrations in encoding of input may involve difficulty in screening out information and inhibiting responses to irrelevant stimuli. There may be reciprocal deficits in response facilitation to salient stimuli.

Various ERP indices have been examined in schizophrenia—including the P50 (Erwin et al. 1991; Freedman et al. 1991) and startle prepulse inhibition (PPI; Braff et al. 1992)—that suggest failure of inhibitory processes. Later potentials related to detection of deviant or novel stimuli, including the N100, mismatch negativity (MMN), and P300, also show abnormalities in schizophrenia. The N100 is an obligate response sensitive to the physical characteristics of a stimulus but not to its context. By contrast, the MMN is elicited by deviant or novel sounds presented amid repeated trains of identical tones. It reflects sensory or echoic memory processes that facilitate response to unexpected environmental changes. Auditory MMN originates in the auditory cortex and is *N*-methyl-D-aspartate (NMDA) sensitive (Javitt et al. 1996). A semblance of the MMN has been described in the hippocampus and thalamus as well (Alho 1995). The most widely studied late ERP is the P300 (Patel and Azzam 2005; Polich 2004). The P300 reflects higher-order processing of a deviant or novel stimulus that surpasses a threshold to elicit orienting (P3a) or matches with a consciously maintained working memory trace (P3b). Analogs of these ERPs have been established in rodents, allowing experimentation not feasible in humans. Latencies are shorter in rodents, but the P20, N40, MMN, and P120 in mice share stimulus and pharmacological response properties with the human P50, N100, MMN, and P3a, respectively (Connolly et al. 2003; Siegel et al. 2003; Umbricht et al. 2004).

The established ERP methods highlighted above examine latencies and amplitudes of averaged evoked responses. Newer measures, which characterize electroencephalogram (EEG) activity in terms of underlying constituent oscillations, more directly represent the synchronized activity of aggregate neuronal assemblies. Evoked oscillations (time- and phase-locked to stimulus) and induced oscillations (loosely time-locked, not phase-locked) are thought to reflect different dynamic neurophysiological processes (Pfurtscheller and Lopes da Silva 1999). Scalp-recorded evoked oscillations reflect the summed postsynaptic potentials of local assemblies of cortical pyramidal neurons. Induced oscillations reflect changes in the dynamic interactions within and among brain structures. These interactions may be subcorticocortical or corticocortical and may underlie dynamic processes such as long-range integration, feature binding, or memory formation (Bastiaansen and Hagoort 2003). Gamma (40 Hz) and theta (4–7 Hz) frequency oscillations, in particular, appear to be intrinsically involved in the processes of stimulus perception, integration, novelty detection, and recognition. Induced gamma oscillations are proposed to "bind" the spatially and temporally discrete neuronal representations of features of a complex stimulus (Bertrand and Tallon-Baudry 2000; Pantev et al. 1991). The growing literature on the gamma band suggests reduced oscillatory power and decreased phase synchrony in schizophrenia, associated with disturbances in the cognitive processes of feature binding and perceptual integration in both the visual (Spencer et al. 2003) and auditory modalities (Lee et al. 2003). Theta oscillations are observed consistently in the hippocampus, where long-term potentiation depends on the phase of the theta rhythm (Sederberg et al. 2003). Induced theta oscillations are also increased diffusely in the cortex during working memory tasks (Raghavachari et al. 2001) and frontally during orienting to novel stimuli. The theta literature in schizophrenia is limited. Notably, the neural mechanisms—glutamatergic and γ aminobutyric acid (GABA)–ergic—that regulate both synchronized gamma and theta rhythms are implicated in the pathophysiology of schizophrenia. Thus, disturbances in glutamatergic and GABAergic function could provide the neurophysiological basis for impairments in sensory evoked potentials, MMN, and synchronized rhythmic EEG oscillations in schizophrenia.

NEUROIMAGING

Advances in neuroimaging technologies have created opportunities to examine schizophrenia as a brain disorder, and investigators have applied diverse methods to study brain structure and function (Gur et al. 2007a). With progress in quantitative computational anatomy methodologies we are at the cusp of an exciting era in neuroscience research that can capitalize on the ability to study the living brain with refined approaches both for hypothesis testing and for exploration. In vivo measurement is afforded by magnetic resonance imaging (MRI) examining neuroanatomy through structural MRI (sMRI), connectivity through diffusion tensor imaging (DTI), and neurochemistry through magnetic resonance spectroscopy (MRS). MRI also enables examination of brain physiology using functional MRI (fMRI) methods that measure changes in signal intensity attributable to cerebral blood flow. Other functional neuroimaging methods include positron emission tomography (PET), which enables measurement of local cerebral glucose metabolism, blood flow, and receptor function. Single photon computed emission tomography (SPECT) can also be used to measure cerebral perfusion and receptor function.

Structural Imaging

An extensive literature of whole-brain volume and specific regions of interest documents consistent morphometric differences between patients with schizophrenia and healthy people. Structural neuroimaging studies with MRI have highlighted diffuse reductions in cortical gray matter volumes as well as diverse but selective regional abnormalities in schizophrenia (Gur et al. 2000a, 2000b; Konick and Friedman 2001; Nelson et al. 1998; Shenton et al. 2001; Wright et al. 2000). Most consistent have been reports of ventricular enlargement and reduced volumes of temporal lobe, superior temporal gyrus, and medial temporal lobe structures. Somewhat less consistent have been reports of abnormal volumes of prefrontal cortex, parietal lobe, thalamus, basal ganglia, cerebellar vermis, and olfactory bulbs, among others regions. Differences in reported results can be attributed to methodologies applied. For example, morphometric prefrontal studies differed in magnetic field, scanning parameters, slice thickness and contiguity, image processing, and regions examined. Consequently, findings seem inconsistent, with some noting no differences between patients and healthy participants and others observing volume reduction in gray matter, white matter, or both tissue compartments. Relatively fewer studies have related subregional volumes to clinical or neurocognitive measures. These studies support the hypothesis that increased volume is associated with better performance (Antonova et al. 2004).

Automated methods for regional parcellation and voxel-based morphometry can now efficiently yield information on the entire brain, permitting validation of reported findings and identification of new possible regions. Such studies corroborate the region of interest approach showing gray matter density reductions in medial temporal lobes and the superior temporal gyrus (Honea et al. 2005). There are also replicated associations between superior temporal gyrus volume and positive symptoms and between medial temporal lobe volume reduction and memory impairment (Gur et al. 2007a). Furthermore, based on morphological parameters, it is possible to apply high-dimensional nonlinear pattern classification techniques to quantify the degree of separation of patients with schizophrenia and healthy control subjects. Such procedures enable testing the potential of sMRI as an aid to diagnosis. In a study of patients with schizophrenia and healthy control subjects, such a procedure demonstrated average classification accuracy of 82% for women and 85% for men (Davatzikos et al. 2005). While such automated methods are promising, further investigation is needed in their potential integration into diagnostic procedures.

The abnormalities evident in brain anatomy should be considered in relation to several potential confounding factors including illness chronicity, treatment with antipsychotic medications, and comorbid diagnosis such as substance abuse. The study of first-episode schizophrenia provides an opportunity to examine if morphometric abnormalities are evident early in the course of illness. A recent review of sMRI studies in first-episode schizophrenia confirms only a reduction in the volumes

of the whole brain and of the hippocampus (Vita et al. 2006). There is therefore a need for additional studies of recent-onset patients to determine if other abnormalities are evident at that time or if they are progressive (Ho et al. 2003).

Distinguishing the effects of illness duration from the effects of ongoing antipsychotic treatment is likely impossible. Most MRI studies that examined the specific regions of interest also evaluated possible relationships with antipsychotic medications. An association with treatment has been reported for the basal ganglia, where an increase of up to 20% in the volume of the globus pallidus has been related to first-generation (typical) antipsychotic medication dose (Wright et al. 2000). For second-generation (atypical) antipsychotics, there is an insufficient body of literature to document specific effects on neuroanatomy. In addition, because substance abuse is so common in schizophrenia, the possible effects of such substances merit consideration. Alcohol abuse has diffuse effects on the brain, with greater impact on the prefrontal cortex than on the temporal lobe, which is the area with the greatest volume reduction in schizophrenia. Moreover, the volume abnormalities are present in patients with no history of alcohol abuse. The potential effect of other substances, such as cannabis, on brain structure is unclear, and volume reduction is evident in patients without a history of cannabis abuse.

The study of people at risk for schizophrenia is an additional strategy to evaluate vulnerability markers for the disorder. Early MRI studies that applied the region of interest approach focused on the amygdala and hippocampus. These found volume reduction in first-degree relatives compared with control subjects, with the family members showing a degree of volume reduction intermediate to that shown in patients and control subjects. Literature reviews and meta-analysis concluded that reduced hippocampal volumes were likely to be a vulnerability marker for schizophrenia (Boos et al. 2006; Lawrie et al. 2004).

Diffusion Tensor Imaging

DTI examines white matter integrity and is a more recent addition to structural measures. The availability of DTI enhances the ability to evaluate compartmental brain tissue abnormalities. Although gray matter volume deficits are more marked than white matter abnormalities in schizophrenia, reduced anisotropy, a measure of directionality of flow of water molecules in axons, providing an index of white matter integrity, is observed with DTI in multiple brain regions. The application of this rapidly developing technology is relatively new, and different approaches are used for data acquisition and analysis. Thus, a consistent literature in schizophrenia has yet to emerge. Abnormalities have been reported in interhemispheric connectivity, as well as in intrahemispheric connectivity among frontal, temporal, and occipital lobes via association fibers (Foong et al. 2002; Kubicki et al. 2005). It is possible that white matter structures may be disorganized in schizophrenia rather than reduced in size (Kanaan et al. 2005). With the growing efforts to understand brain development in infancy and childhood through the application of MRI technology (Giedd et al. 1999; Matsuzawa et al. 2001), the neuroimaging literature in schizophrenia is consistent with diffuse disruption of normal maturation.

Magnetic Resonance Spectroscopy

MRS is a noninvasive method for investigating brain metabolites. Most of this research has focused on investigating phosphorus (^{31}P MRS) and proton-containing metabolites (^{1}H MRS). Proton MRS metabolites such as *N*-acetylaspartate (NAA), which may provide a measure of neuronal integrity, are reduced in schizophrenia, especially in the hippocampus and frontal cortex (Steen et al. 2005). NAA reductions have been associated with decreased cortical volume and correlate with clinical features of the disorder, including illness duration, negative symptoms, and cognitive deficits (Keshavan et al. 2000; Stanley et al. 2000). Notably, NAA reductions have been observed in first-degree relatives of patients with schizophrenia and in prodromal cases and therefore may represent an indicator of vulnerability to the illness (Jessen et al. 2006; Tibbo et al. 2004).

^{31}P MRS studies in neuroleptic-naive first-episode patients suggest increased membrane breakdown with reduced membrane generation throughout the course of illness (Jensen et al. 2004; Stanley et al. 1995). Such changes are commonly evident during cell generation, synaptogenesis, and degeneration and may reflect diverse processes affecting the brain of patients with schizophrenia. Notably, adolescents at genetic risk for schizophrenia manifest membrane alterations similar to those observed in patients early in the course of illness.

Neuroreceptor Imaging

PET and SPECT provide an important avenue for examining in vivo neurochemistry. The investigation of receptor function with PET followed progress with in vitro binding measurements and autoradiography. Early ligand studies in schizophrenia examined primarily dopamine receptors, especially dopamine$_2$ (D_2). Results were somewhat inconsistent, most likely because of differences in patient populations, ligands, and modeling methods used (Andreasen et al. 1988). As neuroleptic-naive patients participated in such studies, the samples were still relatively small, with fewer than 20 patients per study. However, several reviews concluded that increases in both D_2 receptor density and affinity are present in schizophrenia.

A consistent literature has emerged indicating increased presynaptic dopaminergic turnover in schizophrenia. Such studies measured striatal fluorodopa uptake as an index of increased dopa decarboxylase activity and greater presynaptic dopamine turnover in the striatum. Increased activity of dopamine neurons in the striatum appears to be associated with clinical status and is more evident during acute exacerbations and presence of positive symptoms (Erritzoe et al. 2003). Such effects are consistent with studies of neuropharmacological stimulants, such as amphetamine, and cannot be attributed to antipsychotic medication, as approximately half the studies were conducted in medication-free (including neuroleptic naive) patients.

Increased striatal dopamine, most evident in patients with active psychotic symptoms, has been related to the positive symptoms of schizophrenia. More recently, neuroreceptor studies have related dopamine function to cognitive processes in schizophrenia. Cortical dopamine transmission via dopamine$_1$ (D_1) receptors may play a role in impaired working memory and negative symptoms (Abi-Dargham 2004), whereas striatal dopamine activity via D_2 receptors may modulate response inhibition, temporal organization, and motor performance (Cropley et al. 2006).

Receptor imaging by PET and SPECT allows investigation of in vivo targets for antipsychotic drug action (Talbott and Laruelle 2002). It is now known that extrapyramidal (parkinsonian) side effects of first-generation antipsychotic drugs result from high striatal D_2 receptor blockade (~75%), whereas second-generation antipsychotic drugs produce therapeutic benefit in relation to modest and transient striatal D_2 receptor occupancy levels (~65%). These neuroimaging observations point to a rationale for the use of relatively low doses of first-generation antipsychotics and equivalent doses of second-generation antipsychotics (Tauscher and Kapur 2001), although use of neuroimaging to determine dosage ranges in a given patient is far from practical. Neuroreceptor PET and SPECT studies are valuable research tools that can help examine compounds that may regulate or stabilize dopamine, as well as nondopaminergic pathways—such as serotonin, glutamate, and GABA—that may offer promising targets for drug development.

Functional Imaging

The early emphasis on "hypofrontality" in schizophrenia has been refined. The transition from isotopic methods, such as PET, to fMRI for measuring regional brain activation has offered several advantages, including higher spatial and temporal resolution, noninvasiveness, lack of ionizing radiation, direct correlation with anatomical imaging, greater repeatability, and economy. Consequently, numerous studies have applied neurocognitive paradigms in fMRI aimed at dissecting complex behavior. Most of these studies have been in healthy people, applying the blood oxygenation level–dependent (BOLD)

method using blocked designs and, in recent years, event-related paradigms. Diverse neurobehavioral probes have been applied in activation paradigms designed to elucidate the underlying brain circuitry in schizophrenia. Tasks applied have evaluated executive function, such as attention, abstraction, and working memory, as well as declarative and procedural memory, language, spatial, sensorimotor, and emotion processing.

A potential strength of activation studies is the ability to relate the extent of activation to performance obtained "on line." However, relative underactivation in patients who have difficulties performing a task may reflect either a deficit in underlying processes related to that task or a lack of engagement (Davidson and Heinrichs 2003; K. Hill et al. 2004). PET and fMRI studies that attempted to correct for patient impairment by balancing performance of patients and healthy control subjects often failed to find hypofrontality, and some even found hyperfrontality (Honea et al. 2005).

In two recent reviews, 12 N-back (working memory) fMRI studies and 18 episodic memory studies with PET or fMRI found hypofrontality in dorsolateral and inferolateral prefrontal cortex, respectively (Achim and Lepage 2005; Glahn et al. 2005). Hyperfrontality was also reported in medial areas, including the (dorsal) anterior cingulate. Antipsychotic medication is likely to normalize performance on these tasks and hypofrontality (Davis et al. 2005). Regarding the temporal lobe, studies noted increased temporal lobe cortical activity in SPECT and PET studies (Zakzanis et al. 2000), as well as bilateral reductions in perfusion in the medial temporal lobes. Perhaps a hypothesis that will incorporate these findings will evaluate the interaction between laterality and frontality. The relations between frontal and temporal activity merit further investigation and have been related to the hypothesis of decreased connectivity in schizophrenia (Stephan et al. 2006). PET, SPECT, and fMRI studies of disconnectivity are also supported by electrophysiological findings of reduced coherence and gamma asynchrony in schizophrenia (Uhlhaas et al. 2006).

The application of neurobehavioral probes during functional imaging studies has contributed to the effort to investigate involvement of defined neural systems in the pathophysiology of schizophrenia (Gur et al. 1992). Such neurobehavioral probes document deficits in performance associated with abnormal brain activation and implicate the ventromedial temporal lobe, prefrontal cortices, and limbic subcortical nuclei mediating memory, executive functioning, and attention. These systems are characterized by dynamic plasticity, high connectivity, and vulnerability to insult (Arnold and Trojanowski 1996c; Harrison 1999), consistent with the hypothesis that abnormal plasticity is a core neurobiological feature of schizophrenia. Such fundamental mechanisms of abnormal structural, molecular, or physiological plasticity should be evident throughout the central nervous system (CNS) but may be most prominently expressed in neural systems mediating the highly activity-dependent cognitive processes of attention, memory, and executive functioning.

GENETICS

Schizophrenia is a heritable complex brain disorder. Although the mode of inheritance is unknown, the disorder likely results from multiple genes of variable effect interacting with environmental factors. Linkage for schizophrenia has been reported in several regions: 1q32–q41 (Hovatta et al. 1999), 5q31 (Schwab et al. 1997), 6p24–p22 (Straub et al. 1996; Wang et al. 1995), 6q25.2 (Lindholm et al. 2001), 6q13–q26 (Cao et al. 1997), 8p21 (Blouin et al. 1998), 8p23.3 (Suarez et al. 2006), 10p15–p11 (Faraone et al. 1998, 1999), 13q32 (Blouin et al. 1998), 10q22 (Fallin et al. 2003), 10q25.3–q26.3 (Williams et al. 2003), and 22q12–q13 (Brzustowicz et al. 2000; Pulver et al. 1994a, 1994b). While some independent samples have detected linkage in the same or overlapping regions (6p24–p22, 6q13–q26, 10p15–p11, 13q32, 22q12–q13), many have failed to do so (Blouin et al. 1998; Cao et al. 1997; Moises et al. 1995; Schwab et al. 1995a, 1995b, 1998). Lack of overlap may reflect false-positive results or genetic heterogeneity. A meta-analysis of 20 published genomewide scans revealed evidence for linkage on chromosome 2q (C. M. Lewis et al. 2003). Eleven additional loci had suggestive linkage. Because power to detect linkage is limited for genes of intermediate or small

effect size (Risch and Merikangas 1996), these variable findings are not surprising. It is noteworthy that several of the genes identified are directly linked to glutamatergic presynaptic or postsynaptic functioning, and others can be indirectly linked.

Association studies have used primarily functional, rather than positional, candidate gene markers (Shirts and Nimgaonkar 2004). Recent studies report some consistent associations, possibly due to evaluation of positional candidate genes, such as *dysbindin, neuregulin 1,* and *G72* (Harrison and Weinberger 2005; Owen et al. 2005). The risk conferred by associated alleles is modest (odds ratio [OR] ~1.2). The primary risk alleles have not been identified at these genes. Because schizophrenia is phenotypically heterogeneous (Gottesman and Gould 2003), it may be helpful to identify variables correlated with liability. A complementary approach to dissecting the genetic architecture of schizophrenia is to examine the neurobiological traits associated with genetic susceptibility. Here the phenotype is not a clinical diagnosis but a neurobiologically defined trait. Given the heterogeneity of schizophrenia at the phenotypic and likely genotypic levels, analyzing neurobiological phenotypes may improve power by constraining some heterogeneity. Whereas an unequivocal clinical diagnosis may be difficult to establish, quantitative neurobiological phenotypes can be reliably measured in family members. Therefore, chromosomal regions showing inconsistent linkage results, or subthreshold LOD scores with the clinical phenotype, may yield stronger linkage to a neurobiological phenotype. The challenge is selection of informative endophenotypic markers that will efficiently lead to a mechanistic model of schizophrenia. The neurocognitive measures tap neural systems that can be directly studied with structural and functional neuroimaging.

The potential of neurocognitive measures as markers of genetic liability is suggested by the presence of intermediate deficits in unaffected family members of schizophrenia probands (Calkins et al. 2005; Egan et al. 2001a; Thompson et al. 2005). Supporting an additive model, simplex families (those with one individual is affected) have less impairment than multiplex families (those with two or more individuals affected) in language processing (Shedlack et al. 1997), intelligence, verbal learning and memory, visual reproduction (Faraone et al. 2000), visual working memory (Tuulio-Henriksson et al. 2003), verbal learning, delayed visual recall, and perceptual–motor and pure motor speed (Hoff et al. 2005). These results are consistent with several recent reports showing significant heritability of these features (Gur et al. 2007b). Such findings support the role of neurocognitive measures in molecular genetic studies in healthy people (Burdick et al. 2006; de Frias et al. 2005; Plomin and Kosslyn 2001; Posthuma et al. 2005) and in schizophrenia (Bilder et al. 2002; Burdick et al. 2006; Hallmayer et al. 2005; Hennah et al. 2005; Szekeres et al. 2004).

As an example, one candidate gene that has been extensively reported on in the schizophrenia endophenotype literature is the gene encoding catechol-*O*-methyltransferase (COMT). Consistent with the role of COMT in controlling prefrontal cortex phasic dopamine levels (D. A. Lewis et al. 2001; Sesack et al. 1998; Weinberger et al. 2001), subjects with the *COMT* Val/Val genotype performed worse on executive functions (Egan et al. 2001b) and working memory (Goldberg et al. 2003) compared with those with other genotypes. However, subsequent studies suggest a more complex relationship (Tunbridge et al. 2006). Only 1–2 polymorphisms are typically analyzed at each locus, and we need to investigate additional polymorphisms and study their neurobiological context. Furthermore, studies that evaluate a specific cognitive domain and differential deficit require understanding of a profile (Saykin et al. 1991).

By providing quantitative measures of brain structure and function, neuroimaging has become the main approach to the study of brain and behavior in health and disease, fueling the nascent field of imaging genomics (Callicott and Weinberger 2003). Twin studies with sMRI reported heritability estimates greater than 0.90 for whole-brain volume, with lower heritability for regional volumes (Wright et al. 2002). In schizophrenia, the potential of volumetric measures as endophenotypic markers is suggested by reduced brain volume in unaffected siblings compared with control subjects

(Gogtay et al. 2003; Staal et al. 2000) and reduced parahippocampal volume in multiplex, relative to simplex, healthy family members (Seidman et al. 2002). Molecular genetic studies with sMRI have observed smaller hippocampal volumes in Val/Val compared with Met/Met genotypes of *COMT* (Szeszko et al. 2005); an association of disrupted-in-schizophrenia 1 (*DISC1*)/translin-associated factor X (*TRAX*) haplotypes with schizophrenia and reduced prefrontal gray matter, which in turn were associated with impaired memory (Cannon et al. 2005); and reduced dorsolateral prefrontal cortex volume associated with regulator of G protein signaling 4 (*RGS4*) polymorphisms in first-episode schizophrenia patients (Prasad et al. 2005). The application of fMRI in genetic paradigms is more limited and has focused on the *COMT* Val/Met polymorphism and dorsolateral prefrontal cortex activation in healthy people and schizophrenia patients (Egan et al. 2001b; Winterer et al. 2004). Individuals homozygous for the Met allele showed diminished hippocampal engagement during performance of episodic memory encoding and retrieval compared with Val/Val subjects (Hariri et al. 2003). Such studies support use of multimodal imaging in genetic paradigms.

NEUROPATHOLOGY

Neuropathological studies of brain tissues from patients with schizophrenia have reported a wide variety of morphometric, cellular, subcellular, and molecular abnormalities in diverse brain regions. While many findings are controversial or require confirmation, common themes have emerged from the data. Among these themes are abnormal neurodevelopment, abnormal synaptic integrity and plasticity, glutamatergic and GABAergic system abnormalities, mitochondrial dysfunction, and abnormal white matter integrity. Notably, all of these abnormalities occur in the absence of any grossly observable evidence of neural injury or neurodegenerative lesions common in other brain diseases (Arnold et al. 1998).

Abnormal Neurodevelopment

While clinical and epidemiological findings present a compelling case for the role of abnormal neurodevelopment in schizophrenia, characterizing the cellular and molecular mechanism(s) by which this might occur has been a challenge. Neurons are born, migrate, and assume their mature phenotype, and the major axon pathways are laid down in a complex and highly orchestrated process during fetal development and early childhood (Arnold and Trojanowski 1996a, 1996b; Hatten 1999; Nowakowski and Rakic 1981). By the time schizophrenia is clinically expressed, typically in adolescence or young adulthood, much of development has transpired. Limited numbers of new neurons continue to be generated in the adult human brain in certain areas (e.g., the dentate gyrus [Eriksson et al. 1998]), but their number is small and their functionality is still being investigated (Eisch 2002). In contrast, there is ongoing synaptogenesis and synaptic remodeling within all major axon terminal fields throughout life.

Aberrant neurodevelopment in schizophrenia has been inferred by findings from several postmortem research approaches. Among the earliest and most influential neuropathological findings of the modern era were reports of cytoarchitectural disorganization of hippocampal subfields and the entorhinal cortex, a limbic periallocortex intimately related to the hippocampus (Arnold et al. 1991a, 1991b; Conrad et al. 1991; Falkai et al. 1988; Jakob and Beckmann 1986, 1989, 1994; Kovelman and Scheibel 1984). Specific abnormalities have included misalignment of pyramidal cell neurons in ammonic subfields of the hippocampus, abnormal clustering and heterotopic displacement of neurons in the entorhinal cortex, and abnormalities in neuronal densities in different layers of the entorhinal cortex. Similar approaches in other corticolimbic regions, especially anterior cingulate cortex, also have revealed subtle cytoarchitectural differences in schizophrenia compared with control subjects (Benes and Bird 1987; Benes et al. 1992; Chana et al. 2003). However, not all of these findings have been replicated (Akil and Lewis 1997; Altshuler et al. 1987; Arnold et al. 1995; Benes et al. 1991; Krimer et al. 1997; Zaidel et al. 1997).

Another cytoarchitectural approach has been to map the number and position of interstitial white matter neurons lying deep to cerebrocortical gray matter. These neurons are considered to be remnants of the cortical subplate and are thought to reflect incomplete neuronal migration during brain development. Furthermore, because the subplate is important in directing the establishment of normal connectivity, disturbance of the subplate could lead to altered formation of connections. Several groups of investigators reported abnormal numbers or positions of neurons positive for nicotinamide adenine dinucleotide phosphate (NADPH)–diaphorase or microtubule-associated protein 2 (MAP2) within white matter of frontal, temporal, and parahippocampal cortices in schizophrenia, although the specific parameters of maldistribution varied among studies (Akbarian et al. 1993, 1996; Anderson et al. 1996; Kirkpatrick et al. 1999; Rioux et al. 2003).

To explain these phenomena, researchers have proposed that the migration of neurons from the subventricular zone to the appropriate cortical lamina during fetal development is disturbed, that select populations of neurons fail to survive, and/or that neurons fail to generate axonal and dendritic processes appropriately, thus altering their normal orientation or placement. Complex and concerted, generative and regressive neurobiological processes determine the ultimate cytoarchitecture of a given region. In addition to neuronal migration, a host of intrinsic signaling mechanisms responding to extrinsic growth factors and neurotransmitters influence neuron survival, morphology, neurite outgrowth, and patterns of synapse formation. Young neurons that fail to establish adequate synaptic connectivity and access to trophic factors do not survive. Furthermore, the spatial organization of neurons depends not only on the number of neurons that migrate to a particular position and survive but also on the neuropil space in which those neurons reside. Increases or decreases in this space due to its many cellular (e.g., dendritic, axonal, glial processes) and extracellular matrix constituents will affect the spatial distribution of neurons. This has been a major interpretation of reports of reductions in neuropil space in the dorsolateral prefrontal cortex in schizophrenia (Selemon et al. 1998). Finally, environmental factors during growth and development (e.g., infection, ischemic injury, trauma) as well as regressive changes that are part of normal aging may further alter the cytoarchitecture that is observed at postmortem examination.

Abnormal Synaptic Integrity and Plasticity

Synapses have been investigated by a variety of means in postmortem tissues in schizophrenia. At the ultrastructural level, studies described abnormalities in the densities and aggregation of synapses (Aganova and Uranova 1992; Kung et al. 1998; Soustek 1989), dendritic spine morphology and morphometry (Kolomeets and Uranova 1999; Roberts et al. 1996), axon terminal mitochondria (Kolomeets and Uranova 1999; Uranova et al. 1996), and various other changes in axospinous densities and morphologies (for a review, see Honer et al. 2000).

Abnormalities in dendritic arborization and dendritic spines have been reported. Golgi impregnation studies have described decreased spine densities in prefrontal and temporal cortices and in the hippocampus (Garey et al. 1998; Glantz and Lewis 1995; D. A. Lewis and Glantz 1997; Rosoklija et al. 2000), decreased densities of pyramidal basilar dendrites in prefrontal cortex pyramidal neurons (Broadbelt et al. 2002), and increased densities of dentate gyrus granule cell basilar and recurrent dendrites (Lauer et al. 2003). Another index of dendritic densities that has been used in schizophrenia is immunolabeling for the MAP2 that is selectively expressed in the somatodendritic domain of neurons. Several studies have reported a decrease in the density of MAP2 expression in the hippocampus and prefrontal cortex (Arnold et al. 1991b; Jones et al. 2002; Rosoklija et al. 1995, 2005), although other groups have not found this (Cotter et al. 2000; Law et al. 2004). Molecular components of dendritic spines have also been assessed in schizophrenia, with reports of decreased spinophilin messenger RNA (mRNA) in the hippocampus (Law et al. 2004) and decreased mRNA expression of members of the rhoGTPase family, especially Cdc42 and Duo, in dorsolateral prefrontal cortex (J. J. Hill et al. 2006).

Molecules enriched in axon terminals and the presynaptic machinery for neurotransmitter release have been examined in postmortem tissues using a variety of methods, including Western blotting, enzyme-linked immunosorbent assay (ELISA), immunohistochemistry, in situ hybridization, Northern blotting, and quantitative real-time polymerase chain reaction (qPCR), as well as gene expression microarrays. Among the many proteins that have been investigated are synaptic vesicle membrane docking and fusion proteins such as synaptophysin, synapsin, synaptosome-associated protein of 25,000 daltons (SNAP-25), complexins I and II, Rab3a, and syntaxin; synaptic plasticity proteins such as growth-associated protein 43 (GAP-43) and neural cell adhesion molecules (NCAMs); and neurotransmitter system–specific proteins such as vesicular glutamate transporters (VGluTs) and vesicular GABA transporters (VGATs). The regions most commonly examined have been the hippocampus, dorsolateral prefrontal cortex, anterior cingulate, thalamus, and, more recently, the superior temporal gyrus. Most studies reported significant decreases in presynaptic terminal markers, although this has not been without controversy (Eastwood and Harrison 2001; Harrison and Eastwood 2001; Honer and Young 2004; Honer et al. 2000; Mirnics et al. 2001; Sweet et al. 2007).

Glutamatergic and GABAergic System Abnormalities

The glutamate hypothesis of schizophrenia originated with the observations that dissociative anesthetics produce psychotic effects (Luby et al. 1959) and that the NMDA antagonists ketamine and phencyclidine induce schizophrenia-like psychosis and cognitive deficits (Javitt and Zukin 1991). Supporting data in schizophrenia include ketamine induction of eye-tracking abnormalities, impaired prepulse inhibition of the startle response, frontal hypometabolism, abnormal cortical ERPs, and enhanced subcortical dopamine release (Coyle 2004). Molecular neuropathological studies have produced complex and at times conflicting data on glutamatergic synapses in schizophrenia. Most have examined glutamate receptors, with the principal regions of interest being the hippocampus, prefrontal cortex, and thalamus. There are numerous findings of abnormal expression of NMDA receptor subunits NR1 and NR2B; the kainic acid receptor; α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) receptors, phosphorylation of NR1; postsynaptic density proteins PSD95, SAP102, and SAP97; excitatory amino acid (EAA) transporters EAAT1 and EAAT2; and the *N*-acetyl-aspartyl-glutamate (NAAG)–degrading enzyme glutamate carboxypeptidase II (Coyle 2004; Dracheva et al. 2005; Harrison et al. 2003). Although it is currently difficult to weave these diverse findings into a coherent mechanism, the weight of the evidence indicates significant derangement in postsynaptic glutamatergic neurotransmission in schizophrenia.

Compared with data on glutamate, clinical evidence for major GABA involvement in schizophrenia is less compelling. However, substantial postmortem data indicate that GABA markers are abnormal (Benes and Berretta 2001; Blum and Mann 2002; D. A. Lewis et al. 2005; Wassef et al. 2003). In the hippocampus, prefrontal cortex, and elsewhere, there are reports of decreased expression of the GABA-producing enzyme glutamic acid decarboxylase67 (GAD67) mRNA and probably protein (but not GAD65), decreased GABA membrane transporter 1 (GAT1), decreased densities of nonpyramidal (presumably GABA) neurons, decreased calbindin-containing neurons, decreased parvalbumin mRNA, increased $GABA_A$ ligand binding, and increased $GABA_A$ α_1 mRNA levels. In an elegant and compelling set of experiments in localized microcircuitry of the prefrontal cortex, D. A. Lewis et al. (2005) provided evidence for a deficit of GAD67 mRNA expression in presynaptic GAT1 in chandelier interneurons and compensatory changes in postsynaptic $GABA_A$ receptors. They have suggested that these GABA changes may be relatively specific for the prefrontal cortex; however, a similarly detailed investigation has not been conducted elsewhere.

One interpretation of GABA deficits in schizophrenia is that GABA activity is secondarily downregulated due to decreased glutamatergic stimulation. Genetic data associating a growing number of glutamatergic genes with schizophrenia (Harrison and Weinberger 2005) are consistent with primary glutamatergic abnormalities. Other data indicating that a primary glutamate deficit could

account for GABA abnormalities include evidence that administration of NMDA antagonists or surgical ablation of glutamatergic innervation to prefrontal cortex in rodents decreases GABA markers in prefrontal cortex (Cochran et al. 2003; Lipska et al. 2003; Paulson et al. 2003). However, other findings have suggested that GABA deficits are potentially primary (Addington et al. 2005; Caruncho et al. 2004; Guidotti et al. 2000; Hashimoto et al. 2005).

Mitochondrial Dysfunction

Mitochondrial metabolic pathways represent an emerging area of interest in postmortem studies of schizophrenia. Certainly, the long history of findings of brain metabolic abnormalities from PET, SPECT, and fMRI (see "Neuroimaging" section) provide indirect support for the notion that metabolic pathways are dysfunctional in the disease, and, conversely, psychosis and other psychiatric symptoms have been reported as presenting symptoms in bona fide mitochondrial diseases (Fattal et al. 2006).

Mitochondria are cellular organelles, which produce energy as adenosine triphosphate (ATP) via the electron transport chain and the oxidative phosphorylation system and help in the synthesis of other important cell constituents, including amino acids, phospholipids, and nucleotides. A few ultrastructural studies of postmortem tissues have described decreased densities and abnormal morphological profiles of mitochondria in limbic cortices, striatum, and substantia nigra (Kolomeets and Uranova 1999; Kung and Roberts 1999; Uranova et al. 1989). At the molecular level, Middleton et al. (2002) used complementary DNA (cDNA) microarrays to profile the expression of genes in a large number of metabolic pathways in the dorsolateral prefrontal cortex of subjects with schizophrenia and control subjects. They found consistent decreases in the expression levels of genes involved in five specific pathways: ornithine and polyamine metabolism, the mitochondrial malate shuttle system, the transcarboxylic acid cycle, aspartate and alanine metabolism, and ubiquitin metabolism. Prabakaran et al. (2004) used parallel gene expression microarray, proteomic, and metabolomic approaches to examine prefrontal cortex and reported 28 significantly downregulated metabolic pathways and 13 upregulated pathways in schizophrenia. Abnormal pathways included glycolytic and oxidative metabolism, intracellular and vesicle-mediated transport, and pathways involved in defense against reactive oxygen species. In a third microarray study, Iwamoto et al. (2005) reported a global downregulation in mitochondrial genes in schizophrenia and bipolar disorder, although they suggested that this was more related to antipsychotic medication than to disease. Targeted studies of mitochondrial metabolism have reported alterations in mitochondrial enzyme activities for cytochrome c oxidase, succinate dehydrogenase, and NADPH–cytochrome c reductase and mitochondrial complex I expression (Cavelier et al. 1995; Karry et al. 2004; Maurer et al. 2001; Prince et al. 1999; Whatley et al. 1996). While still relatively few, these promising studies indicate a need for increased investigation of mitochondrial metabolic pathways in schizophrenia.

Abnormal White Matter Integrity

Another relatively new area of neuropathological interest in schizophrenia has been oligodendroglia and myelin integrity in schizophrenia. White matter abnormalities have long been hypothesized in schizophrenia. As noted above, clinical neuroimaging and electrophysiological research have yielded evidence of poor functional connectivity between and within brain regions, and some sMRI studies have shown reductions in white matter volumes. Most recently, magnetic transfer and diffusion tensor MRI studies have reported abnormalities in axon membrane integrity and anisotropy.

Postmortem studies have found white matter–related abnormalities at cellular and molecular levels in schizophrenia. A seminal microarray study by Hakak et al. (2001) used a large oligonucleotide microarray to examine dorsolateral prefrontal cortex in an elderly cohort with highly chronic schizophrenia. Although abnormal expression of a variety of genes was reported, the authors were especially impressed with the decreased expression of oligodendroglial genes, including myelin-

associated glycoprotein (MAG), 2',3'-cyclic nucleotide 3'-phosphohydrolase (CNP), myelin and lymphocyte protein (MAL), gelsolin, erbB3, and transferrin. Subsequent studies with qPCR and in situ hybridization continued to find decreased myelin-related gene abnormalities in other samples and brain regions (Dracheva et al. 2006; McCullumsmith et al. 2007) as well as marginal decreases in CNP and MAG using immunohistochemistry (Flynn et al. 2003).

Cellular and subcellular abnormalities of white matter have also been reported. Ultrastructural studies have described decreased compaction of myelin sheath lamellae and abnormal inclusion bodies as well as signs of oligodendroglial degeneration in schizophrenia samples (Uranova et al. 2001). Cell counting studies have reported decreased densities and altered spatial distribution of oligodendroglia in white matter (Hof et al. 2003; Rajkowska et al. 2001).

GENES ASSOCIATED WITH SCHIZOPHRENIA: IMPLICATIONS FOR NEUROPATHOLOGY

As evident from the foregoing sections, the cellular and molecular neuropathological findings in schizophrenia are widespread in location, diverse in nature, and difficult to weave together mechanistically. Much more research needs to be done on multiple levels to advance our understanding of this complex and severe illness. However, recent advances in the genetics of schizophrenia provide some reason for optimism. In the past decade, associations between schizophrenia and a number of specific genes have been reported (for reviews, see Harrison and Weinberger 2005; O'Donovan and Owen 1996; Riley and Kendler 2006), suggesting molecular pathways and pathophysiological mechanisms that, at least theoretically, play diverse roles in the development and ongoing health of the nervous systems.

Among the most highly replicated susceptibility genes are *neuregulin-1, dysbindin,* and *DISC-1,* along with *COMT* discussed previously. While variations in each of these genes confers only a modest increase in risk for the disorder, their discovery nonetheless identifies candidate proteins and molecular pathways that may substantially contribute to the pathophysiology of schizophrenia. This opens the door to a functional genomics of schizophrenia. It is noteworthy that most of these genes play important roles in neurodevelopment, neurotransmission, and neuroplasticity.

Neuregulin-1 is a complex molecule with at least 15 different isoforms that have varied functions in the CNS (Buonanno and Fischbach 2001). Neuregulin-1 plays important roles in neurogenesis, neuronal migration, neuronal survival, axon and dendrite outgrowth, modulation of NMDA signaling via erbB4 receptors, and astroglia and oligodendroglia development via erbB3 receptors, among others. While levels of neuregulin-1 and erbB receptor expression do not appear to be abnormal in schizophrenia, markedly abnormal activation of neuregulin–erbB4 signaling has been found (Hahn et al. 2006).

Dysbindin protein has only recently been characterized (Benson et al. 2001; Li et al. 2003; Talbot et al. 2006). It is neuron-specific; widely distributed in the CNS; present in presynaptic vesicles, postsynaptic densities, neuronal cytoskeleton, and cell nucleus; and important in intracellular trafficking and vesicle formation. So far, dysbindin expression has been found to be decreased in the hippocampus and dorsolateral prefrontal cortex in schizophrenia and may at least in part affect presynaptic glutamate release (Numakawa et al. 2004; Talbot et al. 2004; Weickert et al. 2004).

DISC-1 has been characterized only recently also, after its association with schizophrenia was discovered (Ishizuka et al. 2006). *DISC-1* is preferentially expressed in the forebrain and has multiple isoforms with potential posttranslational modifications. It is present in multiple subcellular compartments, including the actin and microtubule cytoskeletons, centrosomes, postsynaptic densities, mitochondria, and the nucleus. It appears to be important in the centrosome–dynein cascade and cyclic adenosine monophosphate (cAMP) signaling. While its expression level appears to be unaltered in schizophrenia, the expression levels of important binding partners (i.e., fasciculation

and elongation protein zeta-1 [FEZ1], lissencephaly 1 protein [LIS1], and nuclear distribution element-like [NUDEL]) are significantly reduced in schizophrenia (Lipska et al. 2006).

COMT is an enzyme involved in the clearance of catecholamines from synapses and thus could be involved in regulation of neurotransmission related to schizophrenia both in development and maturity (Craddock et al. 2006). A functional polymorphism involving the presence of either valine or methionine at a specific codon affects the enzyme's activity. Variants with methionine have lower activity, and thus, people with two copies of the methionine allele may be expected to have higher dopamine and norepinephrine levels. Given the critical roles these neurotransmitters play in the development of the nervous system and mental functioning especially relevant to psychiatric illness, abnormal levels could have far-reaching cellular, molecular, and clinical effects.

CONCLUSION

Considerable advances with a range of technologies have been made in the efforts to advance the understanding of the neurobiology of schizophrenia. Elucidating the vital neurobiological mechanisms at play is a continuing challenge. Given the complexity of the disorder, we do not expect a single gene, pathological lesion, cellular, molecular or neurochemical abnormality, or even neural system to be nodal to schizophrenia. Indeed, abnormalities are evident at many levels of neurobehavioral and neurophysiological processing and in multiple neural systems—from the cerebellum to diencephalon to diverse primary, association, and limbic cortices to the olfactory bulb and epithelium. However, these diffuse abnormalities, which implicate neurodevelopmental aberrations, are not fully expressed phenotypically until after brain development and maturation are largely completed.

The recognition that the underlying pathological processes of schizophrenia are present throughout the CNS suggests that there may be some core defects in neurotransmission whereby the ability of neurons to respond to and process stimuli is curtailed. However, within the context of global abnormalities, some neural systems are differentially affected. Brain regions with greater vulnerability, such as the hippocampus, prefrontal cortex, and olfactory system, are dynamic and maintain a high degree of plasticity during brain maturation and thereafter. Thus, neuronal plasticity —evident in molecular, chemical, morphological, and physiological modifiability with neural activity—is abnormal in schizophrenia. This may ultimately be manifested in the array of complex features that characterize schizophrenia. However, functions mediated through other neural systems, where greater plasticity is not required, show subtle abnormalities, and motor abilities, sensation, and autonomic functions are relatively spared.

These challenges are further compounded by the absence of suitable animal models for the disorder as currently phenotypically defined, buttressing the need to identify endophenotypes that can be studied in both humans and animals. For example, sensorimotor gating and encoding can be characterized in animals and in humans. The identification of such endophenotypes in schizophrenia that have counterparts in rodents enables investigation of the genetic, molecular, biochemical, anatomical, and physiological aspects of these behaviors in ways not possible in the human. Findings from studies in rodents will continue to provide new information about these behaviors and elucidate the effects of genetic, pharmacological, and behavioral manipulations, which can be pursued in humans. This top-down/bottom-up translational interchange holds great promise for advancing our understanding of the pathophysiology of schizophrenia. As progress is made, we will be in a better position to relate neurobiological processes to major clinical phenotypic characteristics of schizophrenia with the hope of targeted therapeutics that enhance cognition and ameliorate the negative symptoms associated with poor outcome.

Chapter 47. Neurobiology of Anxiety Disorders

NEUROBIOLOGY OF ANXIETY DISORDERS: INTRODUCTION

Our understanding of the neurobiological basis of fear and anxiety continues to improve at a rapid pace. The principal brain regions involved in processing and responding to anxiety are known, many neurochemical systems mediating responses to fearful stimuli have been identified, and new technologies are advancing the study of the interactions of these brain regions with one another. There is also active investigation regarding the relationship between genes and the environment in the development of chronically dysregulated anxiety with the hope that characterizing the neurobiology of anxiety will bring forth therapeutic advances that reduce the significant burden and long-term functional impairment associated with anxiety disorders.

In this chapter, we review preclinical and clinical data relevant to normal and pathological anxiety states. We begin with a brief summary of paradigms of fear learning. We then relate these preclinical paradigms with their neuroanatomical functional localization observed in animals models and more recently in humans with anxiety disorders. Subsequently, we present the major neurochemical systems mediating anxiety processes with a selection of supporting preclinical and clinical data. We then briefly describe findings specific to several of the individual anxiety disorders—panic disorder with and without agoraphobia, specific and social phobias, and posttraumatic stress disorder (PTSD)—and we comment on the state of investigations into the genetic basis of anxiety. We conclude with some of the key questions that will drive future research investigations. The neural circuitry of generalized anxiety disorder (GAD) may be distinct from the disorders noted above (Coplan et al. 2006; Mathew et al. 2008), and will not be further addressed in this chapter. Likewise, although obsessive-compulsive disorder (OCD) is categorized as an anxiety disorder in DSM-IV-TR (American Psychiatric Association 2000), there appears to be sufficient symptomatic and epidemiological heterogeneity between OCD and the other anxiety disorders that it will not be addressed in this chapter (Hollander et al. 2007).

NEURAL PARADIGMS OF FEAR AND ANXIETY

Fear Learning Processes

Investigations into anxiety states depend on a heuristic by which an individual becomes frightened of a novel stimulus and develops means to avoid this stimulus and its implied danger. These means include forming a short-term memory of the stimulus and consolidating this fleeting memory into a long-term memory associated with an avoidant behavior. The retained memories are dynamic and, when evoked by subsequent experience, are subject to change including retention (reconsolidation) or deletion (extinction). Anxiety is the emotional response to new and remembered frightening stimuli.

Formal studies of fear learning processes date back to the experiments of the Russian physiologist Ivan Pavlov in the late nineteenth century. Pavlov's conditional reflex, an involuntary response that was conditionally based on prior experiences, formed the basis for the enduring fear learning paradigm of classical conditioning (Pavlov 1927). Pavlov observed that dogs have habitual responses to salient stimuli, such as salivating when presented with food. He then observed that animals

exposed to a neutral stimulus, such as the sound of a bell, repeatedly paired with a salient stimulus would associate the two stimuli, and the environment in which they were trained, and enact the same habitual response whether presented with the salient stimulus, the neutral stimulus, or even just the environment in which they were trained. Thus, the dog that salivates when presented with food also salivates to the sound of a bell or when entering the training laboratory. The salient stimulus was termed an unconditioned stimulus (US), the neutral stimulus was termed the conditioned stimulus (CS), the habitual response to the US was termed the unconditioned response (UR), and the habitual response to the CS was termed the conditioned response (CR). The association of the CS with the US is learning by explicit cue, whereas the association of the CS with the training environment is learning by context.

The principles of classical conditioning apply to fear learning when the US is aversive and the UR includes the range of motor, autonomic, and endocrine behaviors of the fight-or-flight response. Whereas in healthy people fear learning allows for situational anticipation of danger and generates an adaptive and protective vigilance, people with anxiety disorders frequently mount this response to misinterpreted or neutral stimuli. These maladaptive hypervigilant responses, and their associated avoidant behaviors, are likely to be central to the "fear circuitry" anxiety disorders, including panic disorder, specific and social phobias, and PTSD.

Memory, Consolidation, and Reconsolidation

The conversion of experience into memory is called *consolidation* and relies on changes in synaptic affinity first proposed by the Spanish neuroanatomist Santiago Ramón y Cajal (1894). With brief stimulation, neuronal interconnections transiently strengthen while stimulation of sufficient quantity and appropriate quality causes enduring changes in synaptic strength and structure (reviewed by Bailey et al. 2004). The brief and transient retention of memory is called *sensitization* and occurs due to enhancement of glutamatergic transmission via the α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor, while *long-term potentiation* (LTP) refers to the lasting changes in synaptic affinity in which persistent glutamatergic stimulation of the *N*-methyl-D-aspartate (NMDA) receptor initiates a signaling cascade ending in gene transcription and protein synthesis (reviewed in Malenka and Bear 2004).

The hippocampus and amygdala are key areas in which LTP and, therefore, consolidation, occur. This finding was particularly evident in the case of H. M., a young man who underwent bilateral medial temporal resections to treat his intractable epilepsy and after surgery experienced complete anterograde amnesia and, to a lesser degree, retrograde amnesia (Scoville and Milner 1957). Many animal models have replicated this clinical finding, and hippocampal LTP was recently documented in an in vivo mouse model (Whitlock et al. 2006).

As in Pavlov's experiments, stimuli that are pertinent, or salient, are more likely to be remembered than neutral events. Fear-inducing or emotion-evoking experiences generate a glucocorticoid and catecholamine flux, as we will describe below, which selectively enhances memory consolidation by activating the basolateral complex of the amygdala, an effect which can be blocked by administration of β-adrenoreceptor antagonists (Roozendaal et al. 2006). This paradigm holds true in humans, where memory for an emotional story is superior to memory for a nonemotional story (Cahill et al. 1994). A study showing increased noradrenergic activity after viewing an emotional story suggests that similar neurochemical signaling may be implicated (Southwick et al. 2002). However, clinical trials studying secondary prevention of PTSD with propranolol shortly after exposure to trauma have been equivocal (reviewed in Pitman and Delahanty 2005).

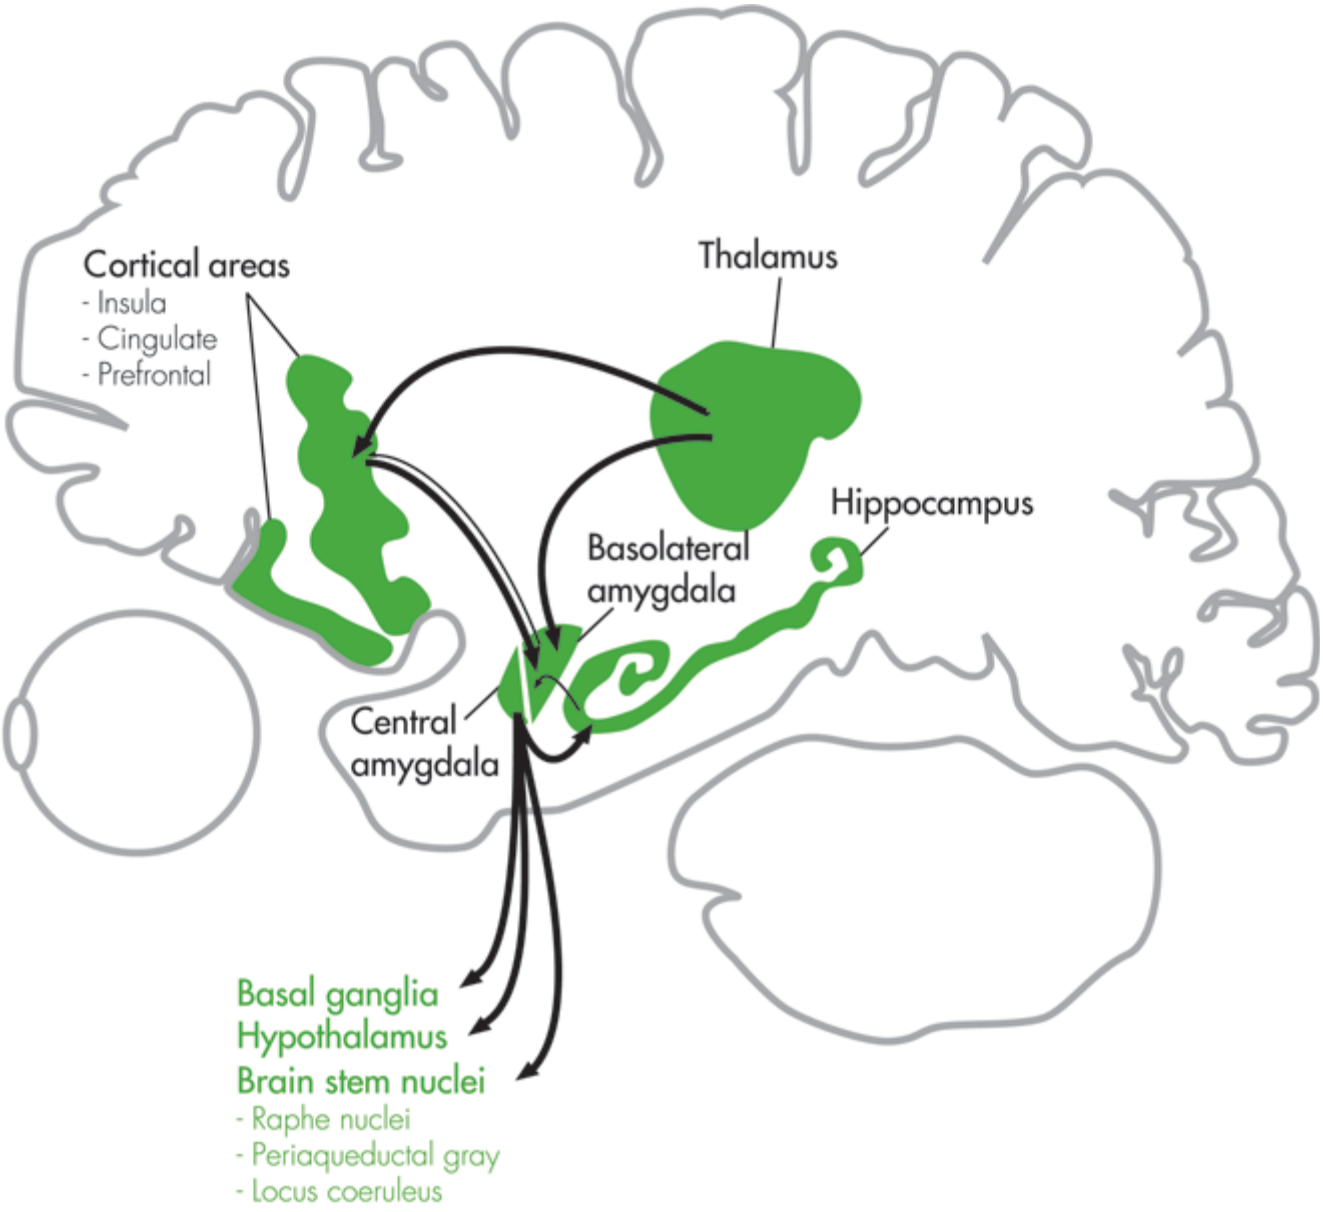
An interesting finding from the late 1960s suggested an additional level of complexity to memory mechanisms. Classically conditioned rats undergoing electroconvulsive shock, which reliably induces retrograde amnesia, 1 day after training (a long enough period of time for consolidation to have

occurred) retained their training, but rats that were reexposed to the CS shortly before electroconvulsive treatment lost their conditioning (Misanin et al. 1968). This finding suggested that when retrieved, long-term memories are subject to modification and must undergo reconsolidation (reviewed in Riccio et al. 2006). Like consolidation, reconsolidation is enacted through a signaling cascade ending in protein synthesis, though these two processes employ independent and dissociable cellular processes (Lee at al. 2004).

Extinction

After Pavlov classically conditioned his dogs to salivate (UR) to the sound of a bell (CS), he found that repeated presentation of the bell (CS) in the absence of food (US) diminished the dogs' salivatory response in a process called *extinction* (Pavlov 1927). Rather than erasing the conditioning process from memory, extinction is a process of integrating new memory that may reverse with a change of context or renewed pairing with the US (Bouton 2004). Like consolidation, extinction involves a cell-signaling cascade and protein synthesis. Glutamatergic NMDA receptors in the amygdala play a key role, and extinction may be blocked by NMDA receptor antagonists like AP5 (Falls et al. 1992) or γ-aminobutyric acid (GABA), an effect that is reversible with D-cycloserine (DCS), an NMDA partial agonist (Akirav 2007).

Extinction is thought to occur by the medial prefrontal cortex's inhibiting the lateral amygdala under hippocampal modulation (Sotres-Bayon et al. 2006). Inactivation of the medial prefrontal cortex by surgical lesion (Milad and Quirk 2002) or local chemical blockade of protein synthesis disables extinction (Santini et al. 2004). Supporting this model, people with PTSD have been found to have depressed ventral medial prefrontal cortex activity during exposure to traumatic reminders (Bremner et al. 1999b).



Clinically, employing extinction to "de-link" neutral stimuli from aversive responses is an important goal of psychotherapy and pharmacotherapy of anxiety disorders. Small clinical trials have shown some benefits to augmenting exposure therapy or cognitive-behavioral therapy with medications to enhance the extinction learning process. In one trial, DCS combined with exposure therapy improved acrophobic symptoms early in treatment and maintained benefit at 3 months (Ressler et al. 2004). This benefit was not observed in the treatment of spider or snake phobias (Guastella et al. 2007a, 2007b). A recent trial of DCS given prior to exposure therapy in people with social anxiety disorder showed significant but modest effects in symptom severity, cognitive dysfunction, and functional impairment (Guastella et al. 2008). A number of larger trials of DCS in several of the anxiety disorders are currently under way.

NEUROANATOMY OF FEAR AND ANXIETY

The neuroanatomical substrates of anxiety detect, process, modulate, and respond to fearful stimuli serially and in parallel with one another, with varying degrees of conscious awareness. Afferent structures are the visual, auditory, vestibular, gustatory, and somatosensory receptors that transmit stimuli to the thalamus. The thalamus distributes signals to brain stem nuclei for automatic reflexes, to the basolateral amygdala via a direct subcortical "short loop" for rapid processing, and to primary and associative sensory, insular, cingulate, and prefrontal cortices that feed back to the amygdala via an indirect "long loop" for higher-order processing and modulation (LeDoux 2000). Olfactory afferents bypass the thalamus and project directly to the entorhinal cortex and the amygdala. Viscerosensory afferents communicate primarily with the nucleus of the solitary tract in the brain stem that relays signals to the central nucleus of the amygdala. Primary sensory cortices and their related association areas form a reciprocal neural circuit with the amygdala and hippocampus by which continued processing, comparison, and learning take place. Expressions of fear are effected through the motor pathways and the neuroendocrine autonomic pathways involving the hypothalamus and pituitary glands, the bed nucleus of the stria terminalis (BNST) and the raphe nuclei, periaqueductal gray

matter, and locus coeruleus of the brain stem. In normal function, this network of afferent, modulatory, and efferent pathways offers protection from physical and psychological threats. When dysregulated, pathological anxiety imposes undue behavioral inhibition and resultant decline in social functioning (Figure 47–1).

FIGURE 47–1. Brain circuits implicated in fear and anxiety.

Copyright © American Psychiatric Publishing, Inc., or American Psychiatric Association, unless otherwise indicated in figure legend. All rights reserved.

A major function of the amygdala is the integration of information from the thalamus and cortical regions into efferent signals *(thick arrows).* Integration of signals occurs in the basolateral amygdaloid complex, whereas efferent responses are mediated by the central nucleus. Reciprocal circuits to the cortex and the hippocampus are particularly relevant to affective modulation and contextual memory *(thin arrows).*

The existence of direct and indirect pathways to amygdalar activation via the short and long loops suggests that the amygdala integrates sensory information with previous experience to determine the significance of complex stimuli and trigger responses based on the determined value of the stimuli. The lasting changes that occur in the amygdala in response to fearful cues occur via LTP in the

pathways involving AMPA and NMDA glutamate receptors, calcium fluxes, and protein synthesis described above (reviewed in LeDoux 2007). The pharmacological inhibition of glutamatergic tone and, to a lesser degree, calcium fluxes has been shown to reduce anxiety in several anxiety disorders (reviewed in Amiel and Mathew 2007; Balon and Ramesh 1996). Recent functional magnetic resonance imaging (MRI) studies of the processing of conscious and unconscious fearful images have implicated subspecificity within the amygdala, with conscious processing modulated in the dorsal amygdala and unconscious processing modulated in the basolateral complex (Etkin et al. 2004). In contrast, contextual fear learning also requires the recruitment of the hippocampus and the BNST (Walker and Davis 1997).

When fear-evoking stimuli are perceived and their processing and modulation do not result in inhibition of the stimulus, the efferent mechanisms of the anxiety–fear circuit generate a range of autonomic, neuroendocrine, and motor responses originally named by Walter Cannon (1915) as the fight-or-flight response. In particular, the lateral nucleus and intercalated cells of the amygdala engage the central nucleus that is the principal output of the amygdala (see Figure 47–1). The central nucleus activates the sympathetic nervous system via the lateral hypothalamus, the parasympathetic nervous system via the dorsal motor nucleus of the vagus nerve, the endogenous opioid system via the periaqueductal gray matter, and the major neurotransmitters of the central nervous system (norepinephrine, dopamine, serotonin, and acetylcholine) via their brain stem nuclei (Schafe et al. 2001). The amygdala also engages the motor system through its connectivity with the motor cortex and the extrapyramidal cortico-striatal-pallidal motor system (McDonald 1991). Interestingly, while the experience of an aversive stimulus generates motor activation, there is functional MRI evidence that anticipation of an aversive stimulus causes marked inhibition of primary motor cortex with reciprocal hyperactivity in the basal ganglia (Butler et al. 2007).

NEUROCHEMISTRY AND GENETICS OF FEAR AND ANXIETY

The anatomical substrates for fear and anxiety described above interact via a diversity of neurochemical messengers. Acute stress triggers the release of these neurotransmitters and neuropeptides, enhancing attention, motor, and memory systems to defend against the present threat and to avoid it in the future. The body upregulates metabolic activity through a surge of catecholamines and glucocorticoids that synergistically increase oxygenation, channel blood flow to the brain and muscle, and make stored energy available. These neurochemical systems operate in a vast and complex network of excitatory, inhibitory, and modulatory circuits. In this section we review the major neurochemical systems that contribute to the fear response under conditions of acute and chronic stress. As anxiety disorders have estimated heritabilities ranging from 30% (Hettema et al. 2001) to 60% when factors of measurement error and gene–environment interactions are controlled (Kendler et al. 1999), we will also discuss data pertaining to genes encoding the receptors that participate in synaptic transmission and modulation of impulses. The heritable component of anxiety is undoubtedly polygenetic, and classical genetic findings that have yielded elegant pathophysiological mechanisms in fields such as oncology and immunology have been elusive.

Noradrenergic System

Noradrenaline/norepinephrine (NE) is a catecholamine that broadly activates cortical, subcortical, and cardiovascular systems via G protein–coupled adrenergic receptors. NE is synthesized from tyrosine peripherally in the adrenal medulla and postganglionic sympathetic efferents and centrally in the locus coeruleus. The locus coeruleus is a small blue-tinted pontine nucleus that constitutes the major noradrenergic cell body aggregate in the brain and is activated most notably in fear states by inputs from the amygdala and the lateral hypothalamus (reviewed in Charney and Drevets 2002). Noradrenergic stimulation of limbic and cortical regions is involved in the elaboration of adaptive responses to stress (Morilak et al. 2005).

Increased NE function accounts for many symptoms of pathological anxiety, such as panic attacks, insomnia, startle, and autonomic hyperarousal (Charney et al. 1987). Cerebrospinal fluid (CSF) NE concentrations are abnormally elevated in PTSD (Geracioti et al. 2001). Platelet α_2-adrenergic receptor density, platelet basal adenosine, isoproterenol, forskolin-stimulated cyclic adenosine monophosphate (cAMP) signal transduction, and basal platelet monoamine oxidase (MAO) activity were decreased in PTSD—findings hypothesized to reflect compensatory responses to chronically elevated NE release (reviewed in Southwick et al. 1999b).

Feedback inhibition appears to play a major role in the regulation of NE activity. Agonists of the presynaptic α_2-adrenergic receptor, including endogenous NE and epinephrine as well as drugs such as clonidine, inhibit the release of NE. α_2-adrenergic receptor antagonists such as yohimbine or idazoxan stimulate the release of NE. People with panic disorder are very sensitive to the anxiogenic effects of yohimbine (Charney et al. 1987). They also have exaggerated plasma 3-methoxy-4-hydroxyphenylglycol (MHPG), cortisol, and cardiovascular responses to the administration of this compound (Charney et al. 1992). People with combat-related PTSD exposed to yohimbine also were reported to have enhanced behavioral, biochemical, and cardiovascular responses (Southwick et al. 1999a). Children with anxiety disorders show greater anxiogenic responses to yohimbine than do nonanxious comparison children (Sallee et al. 2000). The responses to the α_2-adrenergic receptor agonist clonidine are also abnormal in people with panic disorder. Clonidine administration caused greater hypotension and decreases in plasma MHPG, and less sedation, in people with panic disorder than in control subjects (Uhde et al. 1988).

α_2-Adrenergic receptor antagonists have been found to sensitize the locus coeruleus such that excitatory stimuli generate increased responsiveness in the absence of an altered baseline activity, a phenomenon known as sensitization (Simson and Weiss 1988). Clinically, sensitization appears particularly relevant to symptoms of anxiety and PTSD such as tension, irritability, hypervigilance, and exaggerated startle reactivity. The hypothesis that sensitization is implicated in the development of pathological anxiety is supported by clinical studies indicating that repeated exposure to stress is an important risk factor for the development of anxiety disorders, particularly PTSD (Heim and Nemeroff 2001).

Investigation into polymorphisms of the adrenergic receptor has revealed an intriguing insight into the genetic predisposition for the development of pathological anxiety involving noradrenergic synapses. Healthy people homozygous for an in-frame deletion in a subtype of the α_2-adrenergic receptor (α_{2C}-Del322–325) show higher baseline NE levels and more sustained increases in NE levels, heart rate, and anxiety than do control subjects when exposed to yohimbine (Neumeister et al. 2005). A follow-up study of people with this polymorphism and with remitted major depressive disorder found altered recruitment of cortical and limbic brain regions compared with control subjects, suggesting that variability in NE function impacts emotional processing (Neumeister et al. 2006).

Corticotropin-Releasing Hormone

Corticotropin-releasing hormone (CRH) is a principal mediator of the stress response through its well-characterized indirect effects in activating the hypothalamic-pituitary-adrenal (HPA) axis and its lesser-known direct effects in the brain. CRH-containing neurons are located throughout the brain, including the central nucleus of the amygdala, prefrontal and cingulate cortices, BNST, nucleus accumbens, periaqueductal gray, and the noradrenergic locus coeruleus and serotonergic raphe nuclei (Steckler and Holsboer 1999). In response to stress, CRH levels rise and locally activate their target organs via regionally localized CRH_1 and CRH_2 receptors (Sanchez et al. 1999). Animal models studying the differences between CRH_1 and CRH_2 receptor activation suggest opposing function. Mice deficient in CRH_1 display decreased anxiety-like behavior and an impaired stress response (Bale et al. 2002). In contrast, CRH_2-deficient mice display increased anxiety-like behavior and are hypersensitive to stress (Bale et al. 2000; Coste et al. 2000). People with high levels of anxiety and

depression, though not depression alone, and homozygous for a GAG haplotype in the CRH_1 locus, were found to respond more robustly to selective serotonin reuptake inhibitors than those without the same polymorphism (Licinio et al. 2004).

Stress-related CRH secretion inhibits a variety of neurovegetative functions such as food intake, sexual activity, and endocrine programs for growth and reproduction. Exposure to stress in early life can produce long-term elevation of CRH (i.e., exaggerated CRH release) and sensitization of CRH neurons to subsequent stress. The long-term response to heightened CRH is individual and may depend on the social environment, trauma history, and behavioral dominance (Strome et al. 2002). Early exposure of the hippocampus to elevated levels of CRH may be associated with hippocampal damage later in life (Brunson et al. 2001).

CSF concentrations of CRH in people with PTSD are increased relative to those in healthy control subjects (Baker et al. 1999). However, cortisol levels in these samples were not increased, as is the case in most PTSD studies. CSF CRH concentrations are not correlated with plasma cortisol (Baker et al. 1999). High levels of cortisol decrease hypothalamic CRH but increase CRH in areas such as the amygdala (Schulkin et al. 1998).

A number of CRH_1 receptor antagonists are currently being evaluated in preclinical and early clinical trials for their efficacy as anxiolytics and antidepressants and their utility in the treatment of substance abuse. Preclinical data show the promise of one of these compounds, R-121919, in treating symptoms of substance withdrawal (Funk et al. 2007). Although clinical data remain preliminary, R-121919 also may have clinical utility in treating depression and anxiety (Ising and Holsboer 2007). These findings await replication in larger randomized trials.

Arginine Vasopressin

Like CRH, arginine vasopressin (AVP) is a major secretagogue of the HPA/stress system. AVP is produced by the parvicellular neurons of the hypothalamic paraventricular nucleus and secreted into the pituitary portal circulation from axon terminals projecting to the external zone of the median eminence. AVP release is triggered primarily by increasing serum osmolality, hypovolemia, hypotension, and hypoglycemia. AVP has corticotropin-releasing properties when administered alone in humans, a response that may depend on the ambient endogenous CRH level. Following the combination of AVP and CRH, a much greater corticotropin response is seen. The sensitivity of CRH and AVP transcription to glucocorticoid feedback apparently differs, and AVP-stimulated corticotropin secretion may be refractory to glucocorticoid feedback. AVP regulation of the HPA axis may therefore be critical for sustaining corticotropin responsiveness in the presence of high circulating glucocorticoid levels or supersensitive glucocorticoid receptors. Thus, in animals deficient for the CRH_1 receptor, there is a selective compensatory activation of the hypothalamic AVP system, which maintains basal corticotropin secretion and HPA activity. Similar response patterns have been observed following chronic stress, leading to a hypothesis that CRH plays a predominantly permissive role in HPA regulation but that AVP represents the dynamic mediator of corticotropin release.

Extrahypothalamic AVP-containing neurons also have been characterized in the rat, notably in the medial amygdala, where they project to limbic structures such as the lateral septum and the ventral hippocampus and are thought to act as neurotransmitters. Central AVP receptors include V_{1A} and V_{1B}, which are found in the septum, cortex, and hippocampus (Hernando et al. 2001). V_{1A} knockout mice were found to have reduced anxiety in tasks such as the elevated plus-maze and forced swim (Bielsky et al. 2004; Egashira et al. 2007), and conversely, mice overexpressing V_{1A} were found to be more anxious (Bielsky et al. 2005). Preclinical trials of V_{1B} receptor antagonists such as SSR149415 have been promising in showing anxiolytic and antidepressant effects of blocking the activity of AVP on these receptors (Griebel et al. 2002). There is work under way to develop these agents as antidepressants and anxiolytics (Serradeil–Le Gal et al. 2005).

Cortisol

Cortisol is a steroid hormone secreted by the zona fasciculata of the adrenal cortex. Under normal physiological conditions, cortisol levels peak just before awakening and reach a nadir soon after the onset of sleep. With stress, HPA axis activation causes an increase in serum cortisol levels (Morgan et al. 2000). Higher cortisol levels mobilize energy stores, inhibit activity of the growth and reproductive systems, and contain the immune response. Cortisol also may contribute to the recruitment of higher cortical functions to ensure arousal, vigilance, focused attention, rapid recall, and efficient memory encoding and storage. Preclinical data have shown that glucocorticoids can enhance amygdala activity (Charney et al. 1992; Makino et al. 1994), increase the effects of CRH on conditioned fear, and facilitate the encoding of emotion-related memory via an NE-dependent pathway (Roozendaal et al. 2006).

Although transiently elevated serum cortisol may serve adaptive purposes in combating fearful stimuli, long-term exposure to high levels of cortisol have significant deleterious effects, both peripherally and in the central nervous system. Under normal conditions, cortisol feeds back on hypothalamic receptors to inhibit further HPA activation. When this feedback system fails to inhibit cortisol secretion, excessive and sustained cortisol secretion causes hypertension, osteoporosis, immunosuppression, insulin resistance, dyslipidemia, dyscoagulation, atherosclerosis, and cardiovascular disease (Karlamangla et al. 2002). In the brain, a sustained increase in glucocorticoid levels impairs cell survival, alters metabolism and neuronal morphology, and adversely affects hippocampal-dependent cognitive and memory function (McEwen 2000).

There is inconsistent evidence regarding cortisol levels in people with anxiety disorders. People with PTSD generally have normal or decreased 24-hour serum and urine cortisol levels and in some studies have had increased intra-day variability in levels suggestive of increased adrenal reactivity with a reduced threshold for hypothalamic suppression, a finding consistent with pharmacological suppression data (reviewed in Yehuda 2006). A recent small study found that people with PTSD have higher CSF cortisol, which may represent a dissociation between peripheral and central levels (Baker et al. 2005). Similarly, HPA studies in people with panic disorder have yielded inconsistent results, but it appears that there exists a consistent HPA hyperreactivity to novel fear-provoking cues (Abelson et al. 2007).

Neuropeptide Y

Neuropeptide Y (NPY) is a 36–amino acid peptide found mostly in the locus coeruleus, hypothalamus, amygdala, hippocampus, basal ganglia, and midbrain nuclei. NPY is expressed under fearful conditions and appears to inhibit or contain the stress response (reviewed in Heilig 2004). Localized microinjections of NPY in the rat amygdala reduce anxiety and impair memory retention, whereas injections in the locus coeruleus are inhibitory (Flood et al. 1989; Heilig et al. 1989). NPY knockout rats demonstrate increased emotionality in the face of stress and impaired spatial learning (Thorsell et al. 2000), whereas rats in which NPY is overexpressed spend more time in open arms of mazes, implying decreased anxiety (Primeaux et al. 2005). The anxiolytic effects of NPY appear to be mediated in part by glutamate receptor ligands in a manner reversible by Y_1 and Y_2 receptor antagonists (Smiaowska et al. 2007).

The balance between NPY and CRH neurotransmission may be important to emotional responses to stress. NPY counteracts the anxiogenic effects of CRH, and a CRH antagonist blocks the anxiogenic effects of an NPY–Y_1 receptor antagonist. Brain regions that express CRH and CRH receptors also contain NPY and NPY receptors, and the functional effects are often opposite, especially at the level of the locus coeruleus, amygdala, and periaqueductal gray (reviewed in Kask et al. 2002). The reciprocal antagonism appears to be related to bidirectional GABAergic transmission in the BNST (Kash and Winder 2006).

Human studies have found that NPY levels are not significantly different in subjects with PTSD after combat or domestic violence (Morgan et al. 2003; Seedat et al. 2003). Soldiers who underwent distressing interrogation and were found to have clinically significant dissociation had elevated plasma NPY levels (Morgan et al. 2000) that were later found to correlate with improved performance (Morgan et al. 2002). This finding was reinforced by another study that showed that elevated NPY levels were associated with PTSD symptom improvement and may represent a biological correlate of resilience (Yehuda et al. 2006).

Galanin

Galanin is a 30–amino acid neuropeptide involved in emotion-related behaviors including cognition, nociception, sexual behavior, feeding, sleep, and reward (reviewed in Holmes and Picciotto 2006). In rodent studies, galanin collocates with the ascending monoamine systems and, consequently, is found in the locus coeruleus, the raphe nuclei, and the ventral tegmental area and inhibits monoamine, glutamate, and acetylcholine release via three known G protein–coupled receptors (Gal_1, Gal_2, and Gal_3) in the brain stem as well as its subcortical and cortical projections (reviewed in Karlsson and Holmes 2006).

Several preclinical studies have shown a role for galanin in modulating anxiety. Centrally administered galanin produced conflicting results in rats, with some studies showing anxiolytic effects (Bing et al. 1993) and others showing anxiogenic effects (Khoshbouei et al. 2002; Moller et al. 1999). In vivo microdialysis studies have shown that galanin is released in the amygdala in the context of stress and presynaptic α_2-adrenergic receptor blockade, independently of noradrenergic influence from the locus coeruleus (Barrera et al. 2006). In the hippocampus, local overexpression or administration of galanin impairs fear conditioning (Kinney et al. 2002), and Gal_1 receptor–deficient mice show increased anxiety-like behavior.

Preclinical pharmacological studies have shown anxiolytic and antidepressant effects of galanin receptor agonists. Galnon, a nonselective galanin receptor agonist, was shown to have anxiolytic properties reversible with M35, a nonselective galanin receptor antagonist (Rajarao et al. 2006). A similar finding was reported on a forced swim test with rats, suggesting an antidepressant effect of galanin as well (Kuteeva et al. 2007). However, two Gal3 receptor antagonists, SNAP 37889 and SNAP 398299, were found to have anxiolytic and antidepressant properties in several animal models, such as forced swim and stress-induced hyperthermia (Swanson et al. 2005).

To date, only one known study has examined galanin in anxiety disorders. Women with panic disorder and two polymorphisms of the galanin gene were found to have more severe symptoms than women with other haplotypes, a finding that did not extend to the men tested (Unschuld et al. 2008). These findings, in light of the preclinical data reviewed above, suggest a potential role for agents modulating the galanin system in the treatment of anxiety.

Dopamine

Dopamine (DA) is a catecholamine involved in a number of emotional processes including reward, affect, and anxiety. Under conditions of acute stress, DA is released via mesocortical projections in the medial prefrontal cortex and, to a lesser degree, via subcortical projections in the nucleus accumbens and the basolateral amygdala. Stress causes DA to be released and metabolized in the medial prefrontal cortex with an associated inhibition in mesoaccumbens dopaminergic tone (King et al. 1997) via an amygdala-dependent pathway (Goldstein et al. 1996).

These inverse effects on the medial prefrontal cortex and the nucleus accumbens suggest an aversive subjective experience that may play a role in stress-induced depression. In the forced swimming test animal model for depression, mice vulnerable to stress-induced despair stopped swimming almost immediately and were found to have high mesocortical DA metabolism and low mesoaccumbens DA

metabolism compared to normal mice; these findings were reversed by either chemical lesioning of the medial prefrontal cortex or treatment with the tricyclic antidepressant clomipramine (Ventura et al. 2002). Interestingly, lesions of the medial prefrontal cortex inhibit extinction, a situation hypothesized to occur in PTSD (Morrow et al. 1999). Thus, excessive medial prefrontal cortex DA results in helplessness, while insufficient medial prefrontal cortex DA retards extinction, leading to the hypothesis that there exists an optimal range of medial prefrontal cortex DA activation necessary to preserve the reward function of the nucleus accumbens while maintaining the ability to extinguish conditioned emotional memories. These processes may be relevant to understanding the high mood disorder comorbidity observed across all the anxiety disorders.

Clinical research on DA function in anxiety disorders is relatively sparse. To date, investigations into serum and CSF levels of DA or its metabolites have not yielded convincing evidence of alterations in global DA activity. Recently, genetic analyses into polymorphisms of the major DA metabolizing enzyme catechol-*O*-methyltransferase (COMT) have suggested an association between specific polymorphisms and anxiety disorders. In one study, healthy women with the Val158Met COMT polymorphism were found to have higher levels of phobic anxiety (McGrath et al. 2004). A meta-analysis of six case–control studies of COMT polymorphisms did not replicate the Val158Met finding but did find an ethnicity effect, whereby white populations with the 158Val allele and Asian populations with the 158Met allele were found to have a higher incidence of panic disorder (Domschke et al. 2007).

Serotonin

Serotonin (5-HT) is a monoamine neurotransmitter with a diversity of neural, gastrointestinal, and cardiovascular functions. Under conditions of acute stress, regional increases in 5-HT turnover occur in the prefrontal cortex, nucleus accumbens, amygdala, and lateral hypothalamus (Kent et al. 2002). 5-HT release has both anxiogenic and anxiolytic effects, depending on the brain region involved and the receptor subtype activated. One theory is that 5-HT plays a dual role in anxiety, enhancing learned responses to distal threat through projections to the amygdala and the prefrontal cortex while inhibiting unconditioned responses to proximal threats through projections to the periaqueductal gray matter (reviewed in Graeff 2002). 5-HT stimulation of the 5-HT_{2A} receptor is generally anxiogenic, whereas stimulation of the 5-HT_{1A} receptor is generally anxiolytic (Graeff 2004).

Investigation into the function of the 5-HT_{1A} receptor has yielded interesting insights into the role of 5-HT in anxiety. 5-HT_{1A} is primarily inhibitory and is found as a presynaptic autoreceptor in the neurons of the raphe nuclei, whereas it is postsynaptic in the hippocampus, septum, and cortex. 5-HT_{1A} knockout mice exhibit increased anxiety-like behaviors (Parks et al. 1998) which can be reversed if gene expression is conditionally inhibited in adulthood but not in early life (Gross et al. 2002). These findings imply that 5-HT_{1A} receptor activity is required for normal development of the neural circuits regulating anxiety. Clinically, people with panic disorder and social anxiety disorder have a lower density of 5-HT_{1A} receptors in limbic structures including the amygdala, raphe nuclei, and anterior cingulate gyrus (Lanzenberger et al. 2007; Neumeister et al. 2004). This finding was not replicated after exposure to stress in people with PTSD (Bonne et al. 2005).

The 5-HT transporter (5-HTT) and its encoding gene SCL6A4 also play a significant role in the neurobiology of anxiety. Polymorphisms of the SCL6A4 promoter 5-HTTLPR encoding a short (S) or long (L) allele have been linked to mood and anxiety disorders. Carriers of the S allele have lower expression of 5-HTT, decreased 5-HT reuptake, and a higher incidence of anxious traits (Lesch et al. 1996), as well as increased amygdalar activation in response to fearful faces (Hariri et al. 2002, 2005). Children homozygous for the S allele are more shy than controls and may be more vulnerable to developing anxiety disorders later in life (Battaglia et al. 2005). The S allele also confers a depressive and anxious diathesis when combined with early-life stressors. Carriers of the S allele with a history of early-life stress have a higher incidence of depression and behavioral inhibition as children (Fox et al.

2005; Kaufman et al. 2004) and rates of depression as adults (Caspi et al. 2003). A significant number of negative studies also exist in which there is no association between the presence of the S allele, adverse life events, and the incidence of anxiety disorders, confirming the multifactorial nature of the pathophysiology of anxiety.

Similarly, pharmacological dissection of serotonergic systems has not yet established the role of 5-HT in the pathogenesis of anxiety disorders. Panic disorder has been most closely studied, and pharmacological challenges with the 5-HT precursors L-tryptophan (Charney and Heninger 1986) and 5-hydroxytryptophan (DenBoer and Westenberg 1990) or the tryptophan depletion challenge (Goddard et al. 1994) failed to elicit or inhibit panic symptoms in people suffering from panic disorder compared with healthy controls. Fenfluramine, an agent triggering release of 5-HT, has been shown to be anxiogenic and stimulate the HPA axis in people with panic disorder (Targum and Marshall 1989). In sum, it appears that 5-HT dysfunction plays an indirect role in the pathogenesis of anxiety disorders through its modulatory effects on other neurotransmitter systems.

GABA and Benzodiazepines

GABA is the main inhibitory neurotransmitter of the central nervous system and binds to rapid ionotropic $GABA_A$ and $GABA_C$ receptors and slow metabotropic $GABA_B$ receptors most densely concentrated in the cortical gray matter (Bormann 2000). In general, GABAergic tone counteracts excitatory glutamatergic tone, and thus plays a major role in the pathophysiology and treatment of anxiety disorders (Nemeroff 2003). $GABA_A$ and $GABA_C$ receptors contain a chloride channel mediating neuronal hyperpolarization and consequent inhibition. The role of $GABA_B$ receptors is less clearly understood but appears to modulate excitatory transmission and LTP (Chang et al. 2003).

In general, agents that enhance GABA receptor activity are anxiolytic, while those that inhibit GABA receptors are anxiogenic. There are various mechanisms of GABA receptor enhancement and inhibition. Agents that mimic GABA or increase its synaptic concentrations include ethanol, valproate, gabapentin, tiagabine, vigabatrin, and some neurosteroids (reviewed in Kalueff and Nutt 2007). Benzodiazepine agents bind to distinct benzodiazepine (BDZ) receptors on $GABA_A$ receptors, potentiating and prolonging the synaptic actions of GABA binding by increasing the frequency of GABA-mediated chloride channel openings (Smith 2001). The physiological role of BDZ receptors is unknown. Although there is evidence of endogenous BDZ receptor agonists, or endozapines, in unusual conditions including idiopathic recurrent stupor (Tinuper et al. 1994) and hepatic encephalopathy (Cossar et al. 1997), attempts to characterize an endozapine as common as its receptor have been unsuccessful. It is possible that rather than serving a physiological function, the physiological function of the BDZ receptor site is as an intrinsic modulator of GABA receptor activity.

$GABA_A$ receptors contain a chloride channel mediating neuronal hyperpolarization and consequent inhibition. Specific subunits of the $GABA_A$ receptor have been implicated in anxiogenic and anxiolytic phenomena. Preclinical investigations using inverse agonists (Atack et al. 2006), selective agonists (Dias et al. 2005), and behavioral paradigms (Morris et al. 2006) have shown that the α_2 and α_3 subunits have a primary role in modulating anxiety. Furthermore, preclinical models of acute stress have revealed reduced BDZ receptor binding, as well as reduced amygdala and hippocampus expression of the α_2 subunit, which correlate with clinical neuroimaging findings of reduced BDZ receptor binding in people with panic disorder and PTSD (reviewed extensively in Kalueff and Nutt 2007).

Pharmacological modulation of the GABA receptor has revealed interesting findings regarding the role of the GABAergic system in anxiety. Administration of flumazenil, a BDZ receptor antagonist, provokes panic attacks in people with panic disorder, but not in healthy control subjects (Nutt et al. 1990) or in people with other anxiety disorders (reviewed in Nutt and Malizia 2001).

Glutamate

Glutamate is the principal excitatory neurotransmitter in the CNS and also a precursor to the inhibitory neurotransmitter GABA, in addition to its central roles in protein synthesis and metabolism. Glutamatergic networks mediate associative functions of the cortex and hippocampus, sensory relay operations of the hypothalamus, danger-processing functions of the amygdala, and motivation systems in the basal forebrain (Chambers et al. 1999). Glutamatergic neurotransmission is also central to CNS mechanisms of plasticity, such as long-term potentiation or depression and short-term potentiation (Sheng and Kim 2002). Stress-related glutamatergic hyperactivity of sufficient magnitude may lead to increased intracellular calcium levels and neuronal toxicity. Such effects are described in concert with increased glucocorticoid levels and adversely affect varied brain structures, notably hippocampi (Sapolsky 1996). Given the repeated descriptions of reduced hippocampal volume in PTSD, this attribute of glutamate is of particular interest.

Preclinical studies have shown that immediate increase in glutamate efflux in prefrontal cortex and hippocampus occurred after induction of acute stress (Bagley and Moghaddam 1997). NMDA receptors may mediate lasting increases in anxiety-like behavior brought on by the stress of predator exposure. Ketamine (an NMDA antagonist) administration at a subanesthetic dosage in humans induced alterations in identity and perception resembling dissociation, a symptom of PTSD and panic attacks. These phenomena were attenuated by administration of the glutamate antagonist lamotrigine (Anand et al. 2000).

Programmatic investigation into the clinical application of glutamate-modulating drugs for treating anxiety is under way. Small trials have suggested the efficacy of a range of medications including anticonvulsants and the glutamate release inhibitor riluzole (reviewed in Amiel and Mathew 2007). New drugs under investigation include agonists of presynaptic metabotropic glutamate receptors, glycine receptor antagonists, NMDA subtype selective antagonists, and glutamate glial transport blockers.

Neurosteroids

Steroids influence neuronal function through binding to intracellular receptors, which may act as transcription factors in the regulation of gene expression (reviewed in Rupprecht 2003). Several neurosteroids, particularly 3α-reduced metabolites of progesterone and deoxycorticosterone, modulate ligand-gated channels via nongenomic mechanisms (Strömberg et al. 2006). Neurosteroids enhance the function of $GABA_A$ receptors by interacting with NMDA receptors in the central nucleus of the amygdala (Wang et al. 2007) and appear to be anxiolytic in preclinical models (Vanover et al. 2000).

Neurosteroid production is postulated to counteract the negative effects of acute stress. In response to stress, levels of neurosteroids increase rapidly first in the brain and then in the blood. Clinical studies have found that pharmacologically induced panic attacks with cholecystokinin-tetrapeptide (CCK-4) or lactate are associated with decreased 3α-reduced neurosteroids in people with panic disorders, whereas healthy control subjects showed an increase in 3α,5α-tetrahydrodeoxyxortixosterone, also known as allopregnanolone (reviewed in Eser et al. 2006). These findings imply a decreased GABA tone in people with panic disorder.

Progesterone also has been found to be anxiolytic in animals and humans by upregulating allopregnanolone (Reddy et al. 2005) independently of classic progesterone receptors (Frye et al. 2006). Pregnant animals show a decrease in anxiety behaviors correlating with elevated levels of serum progesterone that is reversible with finasteride, an inhibitor of the enzyme 5-α-reductase responsible for the synthesis of allopregnanolone (de Brito-Faturi et al. 2006). Pregnancy has also been found to reduce anxiety and increase allopregnanolone in healthy women (Paoletti et al. 2006) and in women with panic disorder (reviewed in Hertzberg and Wahlbeck 1999). Other studies of serum progesterone metabolite levels in anxiety disorders have been inconsistent, though

premenopasual women with PTSD were found to have reduced CSF allopregnanolone levels (Rasmusson et al. 2006).

Interestingly, drugs that are classically known as 5-HT reuptake inhibitors increase allopregnanolone levels at doses insufficient to block reuptake (Pinna et al. 2006). Further investigations into the interaction between 5-HT and neuropeptides may yield interesting new targets for novel pharmacotherapy of anxiety and affective disorders. The study of the anxiolytic and antidepressant effects of synthetic neurosteroids such as ganaxolone, now being tested in epilepsy, has been proposed (Eser et al. 2006).

Cholecystokinin

Cholecystokinin (CCK) is a neuropeptide, originally discovered in the gastrointestinal tract, found in high density in the cerebral cortex, amygdala, hippocampus, midbrain periaqueductal gray, substantia nigra, and raphe. Its major effect is anxiogenic, and it has important functional interactions with other systems implicated in fear and anxiety (reviewed in Harro 2006).

Rodent models have shown that CCK-like agents induce anxiety, whereas agents that block the effects of CCK are anxiolytic (Bourin and Dailly 2004; Hano et al. 1993). Furthermore, the panicogenic effects of cholecystokinin-tetrapeptide, a CCK_2 receptor agonist acting on the periaqueductal gray matter, are blocked by administration of LY-225910, a CCK_2 receptor antagonist (Bertoglio and Zangrossi 2005; Bertoglio et al. 2007; Netto and Guimaraes 2004; Zanoveli et al. 2004). Pharmacological challenge with CCK increases anxiety in people with panic disorder (Bradwejn et al. 1994) and PTSD (Kellner et al. 2000), but not in people with social phobia (Katzman et al. 2004). CCK antagonists, propranolol, and imipramine seem to reduce the anxiogenic effects of CCK (Bradwejn and Koszycki 1994), suggesting that CCK interacts with the NE system in a manner reversible by the β-adrenergic receptor–downregulating effects of imipramine. There is some evidence of CCK-B gene polymorphisms in subjects with panic disorder, suggesting a possible genetic vulnerability (Hösing et al. 2004).

Although these data suggest that CCK receptor antagonists have a role in the treatment of anxiety, placebo-controlled trials have not shown effects in panic disorder or generalized anxiety disorder (Adams et al. 1995; Goddard et al. 1999; Kramer et al. 1995; Pande et al. 1999; van Megen et al. 1997). Further elucidation of the receptor specificity, regional effects, and neurotransmitter system interactions of CCK may aid in the identification of therapeutic applications.

Endogenous Opioids

The endogenous opioids are a group of neuropeptides including endorphins, enkephalins, dynorphins, and orphanins/nociceptins that bind to opioid receptors. In particular μ-opioid receptors are distributed throughout the brain and are found in higher concentrations in limbic regions including the amygdala, the periaqueductal gray matter, the ventral pallidum, and the cingulate gyrus (Lever 2007). Endogenous opioids have a role in nociception, social attachment, and reward.

Preclinical models have shown that uncontrollable stress induces significant analgesia (Fanselow 1986) and that reexposure to less intense shock in the acute period also results in analgesia (Madden et al. 1977), but that chronic unpredictable stress inhibits nociception, causing hyperalgesia (Pinto-Ribeiro et al. 2004). It also appears that endogenous opioids act on the periaqueductal gray matter in rat models of fear learning, which is blocked with naloxone, indicating that endogenous opioids may be important for extinction (Cole and McNally 2007). An antagonistic interaction with CCK has also been described (reviewed in Hebb et al. 2005).

Human correlates of endogenous opioid abnormalities related to anxiety have also been described. In people with PTSD, β-endorphin levels have been found to be decreased in plasma (Hoffman et al. 1989) but elevated in CSF (Baker et al. 1997). Combat veterans with PTSD were found to have naloxone-reversible pain insensitivity in comparison with combat veterans without PTSD (Pitman et al.

1990). Women who have suffered domestic violence show a correlation between stress-induced analgesia and the development of PTSD hyperarousal 3 months after the trauma (Nishith et al. 2002). Neuroimaging has shown that people with PTSD have increased activation of μ-opioid receptors in the anterior cingulate but decreased activation of these receptors in the amygdala and thalamus (Liberzon et al. 2007). Therapeutic trials have shown that treatment with opiates reduces the incidence of PTSD in hospitalized children by reducing separation anxiety (Saxe et al. 2006), and opioid antagonists reduce PTSD hyperarousal symptoms (Petrakis et al. 2007). In sum, it appears that endogenous opiates offer protection from unbearable pain during acute stress or danger, but that with chronic stress, a dysregulation of the endogenous opioid system occurs characterized by altered nociception and extinction.

Genetic investigations into the endogenous opioid system are preliminary, but individuals with high levels of worry and homozygous for the met158 polymorphism of the COMT allele were found to have regionally blunted μ-opioid response to pain and increased report of subjective pain and distress in comparison with heterozygotes (Zubieta et al. 2003).

NEUROCIRCUITRY OF SPECIFIC ANXIETY DISORDERS

Panic disorder, specific and social phobias, and PTSD share many mechanisms underlying fear and anxiety responses and may best represent the "fear-based" anxiety disorders. The regions most often implicated with psychopathology include the limbic, paralimbic, and sensory association areas. Below we review key findings in these disorders.

Panic Disorder

Panic disorder is characterized by recurrent, short-lived, but intense panic attacks and a continuous but more moderate type of anxiety (termed anticipatory anxiety). Studies in the "resting state" are assumed to represent the latter type of anxiety. Earlier resting-state studies initially found an asymmetry (left less than right) of blood flow and oxygen metabolism in the hippocampus and parahippocampal gyrus (for a review, see Charney and Drevets 2002). Abnormal glucose metabolism in this region, but with the opposite laterality (i.e., elevated metabolism in the left hippocampal/parahippocampal area), was reported in a more recent study (Sakai et al. 2005). However, decreased resting-state bilateral perfusion also was reported in lactate-sensitive subjects with panic disorder compared with control subjects.

Functional imaging of subjects with panic disorder also has been performed during experimentally induced panic attacks. Because states of extreme fear are also observed or induced in healthy control subjects, it is unknown if the neuroanatomy of panic attacks would be similar or different in healthy subjects and people with panic disorder. Regional cerebral blood flow (CBF) increases in the anterior insula, anteromedial cerebellum, and midbrain were observed after sodium lactate infusion–induced panic attacks in people with panic disorder. Anxiety attacks induced in healthy humans with cholecystokinin-tetrapeptide (CCK-4) also were associated with CBF increases in similar regions and the anterior cingulate cortex. Yohimbine administration increased medial frontal CBF in healthy control subjects but decreased relative prefrontal cortical perfusion in people with panic disorder relative to control subjects. People with panic disorder, but not healthy control subjects, had reductions in absolute measures of global CBF under CO_2 provocation (Ponto et al. 2002). In pentagastrin-induced panic attacks, hypoactivity in people with panic disorder, compared with control subjects, was found in the precentral gyrus, inferior frontal gyrus, right amygdala, and anterior insula. Hyperactivity in people with panic disorder was observed in the parahippocampal gyrus, superior temporal lobe, hypothalamus, anterior cingulate gyrus, and midbrain (Boshuisen et al. 2002). Positron emission tomography (PET) studies have shown that doxapram-induced paniclike states are associated with decreased prefrontal activity and increased amygdala and cingulate activation in people with panic disorder, but not in healthy control subjects, further supporting the model that prefrontal inhibition is

important in attenuating anxiety (Garakani et al. 2007).

In a preliminary functional MRI study comparing people with panic disorder and healthy subjects during mental imagery of high anxiety states, people with panic disorder showed increased activity in the inferior frontal cortex, hippocampus, and anterior and posterior cingulate gyrus, extending into the orbitofrontal cortex and encompassing both hemispheres (Bystritsky et al. 2001). In the first report of functional MRI of spontaneous panic attack, a woman with panic disorder was found to have markedly increased activity in the right amygdala (Pfleiderer et al. 2007).

Only a few structural MRI studies have investigated morphometric or morphological abnormalities in panic disorder. Ontiveros et al. (1989) reported qualitative abnormalities of temporal lobe structure in panic disorder, although these findings have not been replicated. Vythilingam et al. (2000) reported that hippocampal volume did not differ between people with panic disorder and healthy control subjects, but the entire temporal lobe volume was reduced bilaterally in the people with panic disorder. However, this finding was difficult to interpret, because when normalized to whole-brain volume, the differences in temporal lobe measures between panic disorder and control samples had magnitudes of 2%. A volumetric MRI study found bilaterally reduced amygdala volumes in patient with panic disorder without associated differences in hippocampal or overall temporal lobe size (Massana et al. 2003). Neuroimaging studies found reduced BZD receptor binding in people with anxiety disorders (reviewed earlier in this chapter in the subsection "GABA and Benzodiazepines").

Phobias

The phobic response is phenomenologically similar to a panic attack. It has been imaged by acquiring blood flow scans while exposing people to their feared object (for review, see Charney and Drevets 2002). A progressive pattern of regional CBF responses was observed during successive scans. Perfusion initially increased in the lateral orbital/anterior insular cortex bilaterally, in the pregenual anterior cingulate cortex, and in the anteromedial cerebellum. During continued presentations of the phobic stimulus, the magnitude of the hemodynamic response diminished in the anterior insula and the medial cerebellum but increased in the left posterior orbital cortex. The CBF increase was inversely correlated with decreases in heart rate and anxiety ratings. In a PET [^{15}O]butanol study of people with simple spider phobia, phobic stimulation elevated regional CBF bilaterally in the secondary visual cortex compared with neutral stimulation but reduced regional CBF in the hippocampus and in the prefrontal, orbitofrontal, temporopolar, and posterior cingulate cortices (Pissiota et al. 2003). A recent functional MRI study (Paquette et al. 2003) reported reversal of phobic (spider) provocation increases in the dorsolateral prefrontal cortex (Brodmann area 10) and parahippocampal gyrus in people with simple phobia after clinically successful treatment with cognitive-behavioral therapy. These authors concluded that effective psychotherapeutic treatment (i.e., cognitive-behavioral therapy) can modify dysfunctional neural circuitry associated with pathological anxiety.

Several functional imaging studies have focused on social phobia. When speaking in public, people with social phobia had elevated CBF in the amygdaloid complex and reduced CBF in orbitofrontal and insular cortices and the temporal pole relative to comparison subjects (Tillfors et al. 2001). It is hypothesized that in social phobia, as in PTSD (see the following subsection, "Posttraumatic Stress Disorder"), exaggerated fear response is related to an absence of cortical inhibition. Another study compared subjects with social phobia scanned either before or after speaking in public (Tillfors et al. 2002). In the anticipation group, increased CBF was found in the right dorsolateral prefrontal cortex, left inferior temporal cortex, and left amygdaloid–hippocampal region, and decreased CBF was found in the left temporal pole and bilaterally in the cerebellum. Anticipatory anxiety in people with social phobia may involve a fear network encompassing the amygdaloid–hippocampal region and prefrontal and temporal areas, much like the anticipatory anxiety neurocircuitry of people with panic disorder.

Another PET study by the same group (Furmark et al. 2002) reported that clinical improvement in

social phobia, obtained by treatment with group psychotherapy or citalopram, was accompanied by similar decreases in provocation-induced regional CBF in the amygdala, hippocampus, and periamygdaloid, rhinal, and parahippocampal cortices. CBF in these regions decreased significantly more in responders compared with nonresponders, particularly in the right hemisphere. Tc-99m hexamethylpropyleneamine oxime ([^{99m}Tc]-HMPAO) single photon emission computed tomography (SPECT) was used to evaluate resting-state regional CBF ratios in a group of 15 people with social phobia before and after treatment with citalopram (Van der Linden et al. 2000). Regional CBF was significantly reduced in the anterior and lateral part of the left temporal cortex; the anterior, lateral, and posterior part of the left midfrontal cortex; and the left cingulum. Results from both treatment studies are conceptually and anatomically similar to those obtained from the above-described treatment studies in simple phobia and panic disorder, suggesting a mutual neurocircuitry for fear responses in diverse anxiety disorders.

Functional MRI studies have been useful in assessing regional brain activity in phobic individuals. In comparison with healthy control subjects, people with social phobia have larger increases of the amygdala (Stein et al. 2002) and anterior cingulate (Amir et al. 2005) blood oxygen level–dependent signal when viewing angry faces rather than happy faces. Arachnophobic individuals experiencing anticipatory anxiety have fMRI hyperactivation of anterior cingulate, insula, thalamus, and visual areas as well as the BNST (Straube et al. 2007). Interestingly, group exposure therapy was found to reduce amygala and insula hyperactivation in arachnophobic subjects over the course of treatment (Schienle et al. 2007). These findings are consistent with the hypothesis of a hyperactive limbic/amygdala response to anxiogenic stimuli in anxiety and stress-related disorders.

Posttraumatic Stress Disorder

Activation brain imaging studies comparing people with PTSD with healthy or trauma-exposed control subjects were expected to detect differences in the amygdala, hippocampus, and medial prefrontal cortex, because it was assumed that there was an exaggerated fear response in the absence of cortical inhibition. Amygdala activation was observed as PTSD subjects were compelled to reexperience trauma (Liberzon et al. 1999; Rauch et al. 1996; Shin et al. 1997). Other studies found no significant changes in amygdala CBF under similar conditions (Bremner et al. 1999a, 1999b; Shin et al. 1999). In contrast to the inconsistencies in amygdala activation, the pattern of CBF changes in the medial prefrontal cortex consistently differentiated between PTSD and healthy subjects, showing increased activation in the latter group (Bremner et al. 1999b; Shin et al. 1997, 1999).

In the infralimbic cortex, CBF decreased in subjects with combat-related PTSD but increased in matched, non-PTSD control subjects during exposure to combat-related stimuli (Bremner et al. 1999b). The findings of decreased anterior cingulate and increased amygdala function after traumatic recall have been interpreted as a failure of cortical inhibition of amygdala-mediated fear responses. Findings from two functional MRI studies support anterior cingulate hypofunction in PTSD, particularly in the emotional component of this structure. Reduced perfusion in the anterior cingulate in PTSD subjects compared with trauma-exposed control subjects was found after activation by the emotional Stroop test (Shin et al. 2001) and traumatic recall (Lanius et al. 2001). Given preclinical evidence that the anterior cingulate and infralimbic cortices play roles in extinguishing fear-conditioned responses (Milad and Quirk 2002), failure to activate the anterior cingulate cortex in PTSD suggests impairment of neural substrate mediation extinction in PTSD.

A preliminary functional MRI study found exaggerated amygdala response in PTSD subjects relative to trauma-matched control subjects during exposure to masked-fearful faces relative to masked-happy faces (Rauch et al. 2000). Because participants were only aware of seeing the mask, the increased activation of the amygdala can be understood as a "bottom-up" phenomenon, suggesting an inherent malfunction in the amygdala regardless of the presence or absence of cortical inhibition.

Structural imaging of hippocampal volume in PTSD was stimulated by preclinical studies reporting hippocampal neuronal loss and dendritic atrophy following exposure to chemical or psychosocial stress (McEwen 1999). Structural MRI studies of PTSD have identified subtle reductions in the volume of the hippocampus in PTSD samples relative to healthy or traumatized, non-PTSD control samples (for review, see Hull 2002; Villarreal et al. 2002). These studies mainly investigated people with chronic PTSD, often associated with comorbid mental disorders, pharmacological treatment, and alcohol and substance abuse, although most studies attempted to control for these factors. However, Agartz et al. (1999) have shown that in the presence of alcohol abuse, the additional occurrence of PTSD has no added effect on hippocampal volume. De Bellis et al. (2000) reported a decrease in hippocampal volume in young adults with adolescent-onset alcohol use disorder.

A few studies did not report hippocampal reduction in PTSD. Prospective longitudinal studies of acute single civilian trauma survivors found no difference in hippocampal volume between healthy trauma survivors and people with PTSD at two time points as well as across time (for review, see Hull 2002). The difference in hippocampal volume in PTSD may apply to specific subtypes of the disorder (i.e., chronic vs. acute trauma), reflect chronic stress associated with long-term PTSD, or indicate a biological antecedent that may confer risk for developing PTSD.

CONCLUSION

Physiological and pathological anxiety likely represent a spectrum of hyperactivation of specific neurochemical axes and neuroanatomical circuits. There are significant genetic contributions to the anxiety diathesis, but undoubtedly the experience of fearful stimuli in the environment plays a major role in inducing, reinforcing, and sometimes generalizing the fear response. We have reviewed polymorphisms associated with clinical findings in the noradrenergic, HPA, dopaminergic, serotonergic, and endogenous opioid systems. There is also active investigation of the genetics of intracellular processes associated with learning and unlearning that will undoubtedly relate to the study of anxiety. In addition, explorations in the field of epigenetics, or nongenomic variations in gene expression and protein synthesis, are just beginning. Evolving technologies of gene arrays and automated screening, as well as the linkage of imaging modalities with genetic research, will offer new insights into the neurobiology of anxiety disorders.

In this chapter, we attempted to provide a framework for understanding these phenomena, linking potential and still largely hypothetical neural mechanisms derived from preclinical research to the neurobiological findings in people with anxiety disorders. We presented data showing an association among neurotransmitters, neuropeptides, and hormones and various states of anxiety. A neurocircuitry apparently shared by many anxiety disorders was illustrated. Several important questions are raised in light of this review:

- Are there qualitative differences in the neurocircuitry of fear and anxiety in pathological versus physiological anxiety?
- How do the neurobiological systems implicated in anxiety change over time and with new experiences?
- How do pharmacological and behavioral interventions alter the neurobiology of anxiety?
- Is the neurobiology of each DSM-IV-TR anxiety disorder distinct, or do they represent subtle variations of a shared etiology?

Continuing research into the epidemiology, genetics, neurochemistry, and functional anatomy of physiological anxiety, pathological anxiety, and the effect of therapeutic interventions will address these questions and inform clinical practice by supporting or refuting currently accepted nosologies and pharmacological and psychotherapeutic interventions.

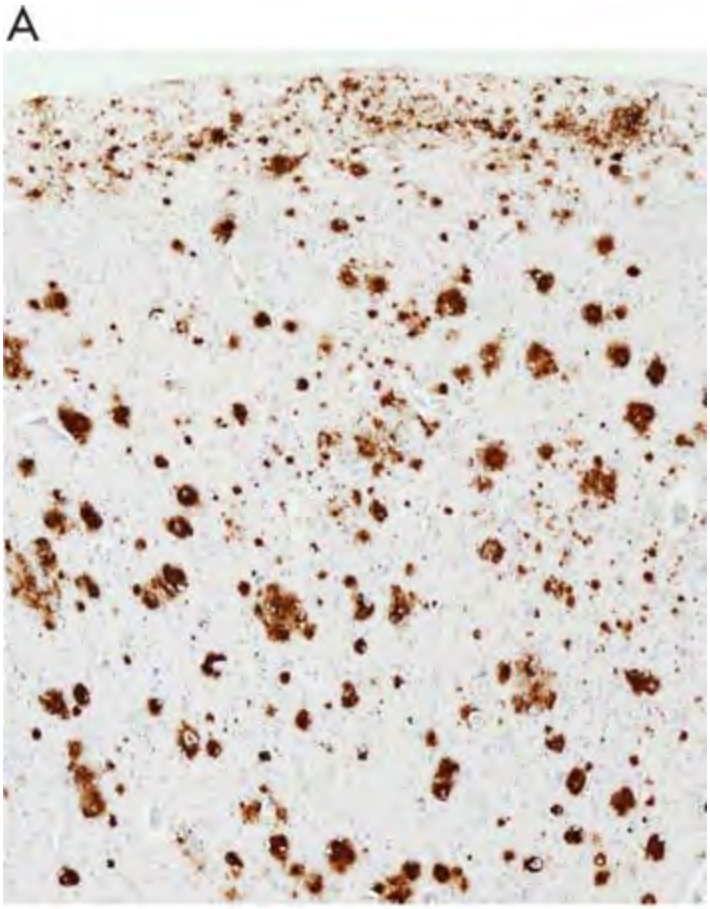
Chapter 48. Neurobiology of Alzheimer's Disease

NEUROBIOLOGY OF ALZHEIMER'S DISEASE: INTRODUCTION

Of the broad spectrum of brain diseases that can produce dementia, Alzheimer's disease (AD) is the most common. AD is a devastating disorder characterized by progressive loss of memory and intellectual abilities, affecting more than 40% of individuals older than 85 years of age. The remarkable increase in disease prevalence that has accompanied the growth of the oldest segment of the population has heightened public awareness and accelerated research efforts to understand the disease. AD has been recognized as a clinical and neuropathological entity for more than 100 years, but specific therapies were unavailable until the development of the first cholinesterase inhibitor, tacrine, about 20 years ago. Since that time, several new cholinesterase inhibitors have been approved for the treatment of AD patients, and novel therapies, such as the *N*-methyl-D-aspartate (NMDA) receptor antagonist memantine, have shown modest benefit in improving cognitive function in patients with AD. Common clinical practice has also embraced the use of high-dose vitamin E as an antioxidant that may provide some neuroprotective benefit. Research on AD funded by the government, private foundations, and the pharmaceutical industry commits billions of dollars annually for achieving better understanding of the disease and for developing more effective treatments. These efforts will inevitably lead to continued improvement in clinical practice in the coming years.

AD is complex, with multiple genetic components, risk factors, neuropathological features, and theories of pathogenesis. This chapter provides an update on our current understanding of the biological basis of the disease and background for understanding the anticipated rapid changes in the clinical approach to AD. Because our understanding of AD is still evolving, it is difficult to predict the form of future clinical applications. Some of these will certainly be surprising. However, the most dramatic advances and changes in clinical management of AD are likely to emerge from the rational development of treatments to modify the basic mechanisms of disease. With this in mind, we begin this chapter by reviewing well-established neuropathological and neurochemical changes observed in AD. These abnormalities are particularly relevant for understanding the rationale for the use of cholinesterase inhibitors and other drugs for ameliorating cognitive, emotional, and behavioral symptoms. Next we examine epidemiological studies that have revealed several risk factors for AD and have offered clues to potentially important mechanisms in disease pathogenesis and possible prevention. AD genetics is a rapidly expanding field, and some of the more salient observations are noted here. We conclude the chapter by considering several theories of AD etiopathogenesis as well as future directions of research and disease therapy. This discussion will certainly require modification and refinement as new research findings emerge. However, these theories provide the rationale for most of the current efforts to develop new therapies that will produce a significant impact on preventing, halting, or perhaps reversing the disease process.



[The authors are grateful to Dr. Marla Gearing for providing photomicrographs and for critical reading of the text.]

PATHOLOGY

The primary pathological hallmarks of AD, described a century ago by Alois Alzheimer (1906), consist of senile (neuritic) plaques and neurofibrillary tangles (Figure 48–1). These morphological changes,

which are visible on silver-stained specimens, provide important clues to the biology of AD. *Neuritic plaques* are complex structures that consist of extracellular aggregates of the amyloid-beta (Aβ) peptide, surrounded by swollen dystrophic neurites and infiltrated by microglia and reactive astrocytes. *Neurofibrillary tangles* are intracellular accumulations of hyperphosphorylated tau, a cytoskeleton-associated protein organized in disease states as paired helical filaments. Grossly, there is often atrophy of the frontal, parietal, and temporal lobes in brains with AD. The medial temporal lobe structures, including the amygdala, hippocampus, and entorhinal cortex, are usually markedly shrunken. While atrophy is not specific to AD, the areas of atrophy reflect the selective vulnerability of certain brain regions and correspond to the microscopic accumulation of plaques and tangles.

(A) Low-magnification view of cerebral cortex showing multiple Aβ-immunopositive plaques. **(B)** Higher magnification of a Bielschowsky silver stain showing argyrophilic amyloid plaques *(arrow)* and neurofibrillary tangles *(arrowhead)* in cerebral cortex. **(C)** High-magnification view of a single neuritic plaque. The central core of the plaque contains amyloid peptides that are surrounded by a clear halo and then swollen silver-positive dystrophic neurites. **(D)** High-magnification view of a neurofibrillary tangle.

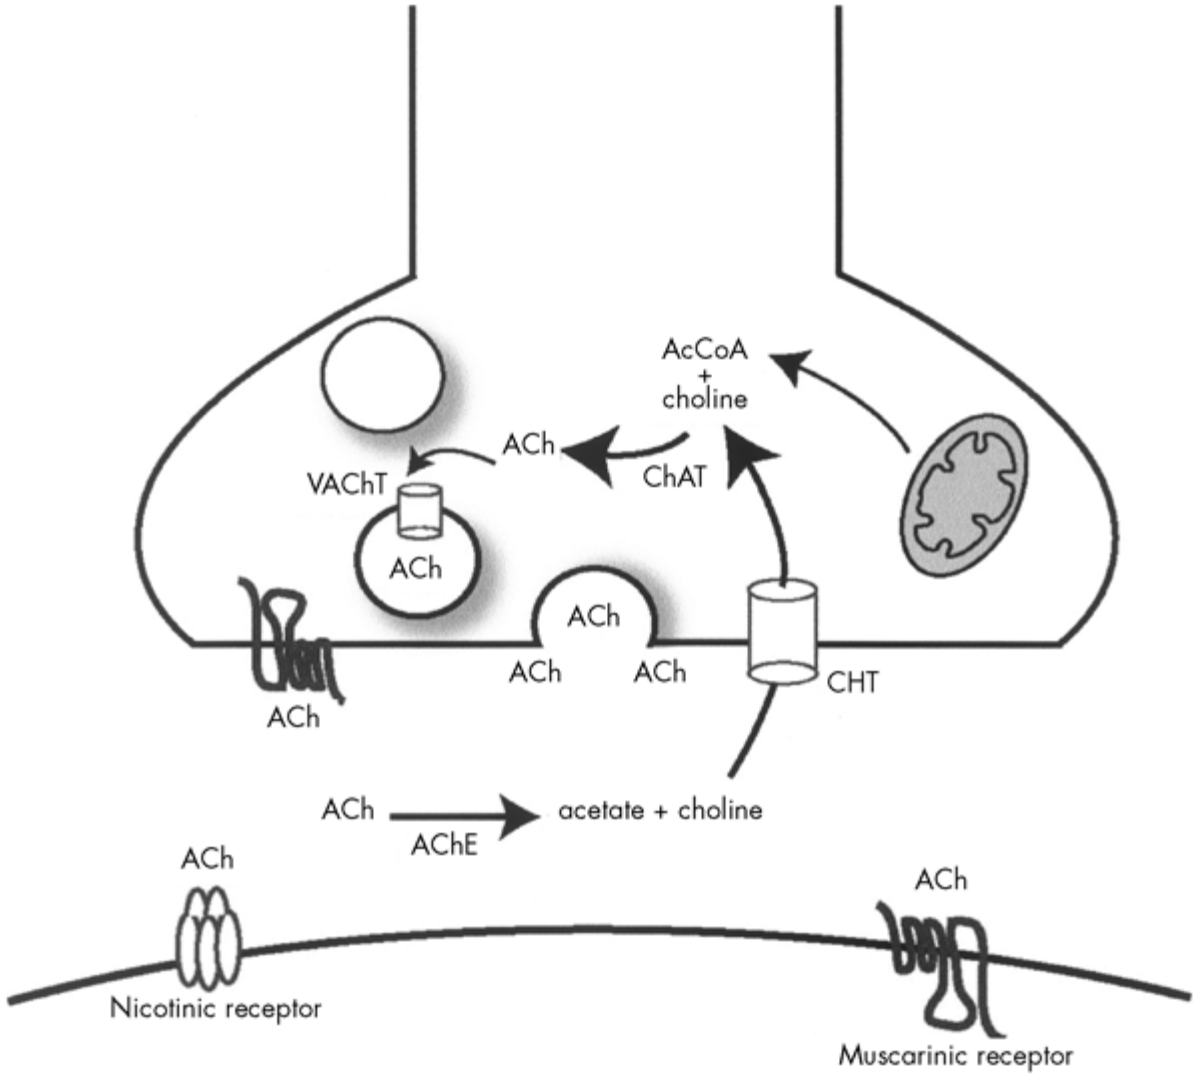
In addition to plaques and tangles, other pathological changes are visible in the AD brain (Terry et al. 1994). Amyloid deposition in leptomeningeal blood vessel walls, known as *amyloid angiopathy,* results in increased frequency of lobar hemorrhages. *Neuropil threads* are short neuronal processes that are marked by silver stains, thioflavin, and tau immunoreactivity, found mostly in cortical regions associated with tangle pathology. *Hirano bodies* are rod-like filaments composed of actin and other microfilaments, most commonly occurring in pyramidal neurons in the hippocampus. *Granulovacuolar degeneration,* detectable by the appearance of large cytoplasmic membrane-delimited vacuoles, is often found in the same regions. These vacuoles also contain cytoskeleton-associated proteins. All of the pathological lesions occur in "normal" aging to a limited extent, but they occur much more frequently in the hippocampus, neocortex, and other areas in AD.

Cellular and synaptic alterations also occur in AD. There is a loss of large neurons, particularly in layer II of the entorhinal cortex, pyramidal neurons in layers III and V of neocortex, cholinergic neurons in the basal forebrain, and in select subcortical nuclei. Loss of synapses is an important change because this pathology presumably results in the disconnection of cortical association areas. Indeed, of all pathological alterations measured to date, synapse loss best correlates with cognitive deficits. There are also a variety of intracellular changes in endomembranous compartments. For example, the biosynthetic machinery, including the Golgi apparatus, is shrunken (Salehi et al. 1994), and there is

an expansion of endosomal compartments (Cataldo et al. 1995, 1996; Nixon 2005). Endosomal changes occur early in the disease, even at preclinical stages in vulnerable neurons, and appear to be intimately associated with genetic factors in AD.

The wide variety of pathological changes raises questions about their sequence of occurrence; that is, a more complete understanding of the disease's pathogenesis rests on the identification of the primary changes that cause the disease versus the secondary changes that occur in later stages of neurodegeneration. This key issue remains unresolved. Moreover, it is possible that there may be several distinct mechanisms that are capable of initiating the pathogenic cascade. For example, genetic studies indicate that mutations in several genes (*amyloid precursor protein* [*APP*], *presenilin 1* [*PSEN1*], and *presenilin 2* [*PSEN2*]) are sufficient to initiate disease and that polymorphisms in other genes can accelerate the process. Ultimately, the development of strategies to modify the course or to prevent the disease demands understanding of the mechanisms by which genetic and environmental factors interact to cause disease. These factors are further discussed in the sections that follow. Advances in understanding the biology of all phases of AD will impact drug development. In particular, the improved understanding of the neurochemical changes has opened the door for the first successful attempts to develop efficacious drugs.

NEUROCHEMISTRY AND NEUROPHARMACOLOGY



Numerous studies have examined the neurochemical changes that occur in the brains of individuals with AD. The most consistent changes involve loss of cholinergic, serotonergic, and glutamatergic markers (Bowen and Francis 1990). The acetylcholine and serotonin neurons are located in the basal forebrain and upper brain stem, respectively, and their degeneration results in the loss of ascending modulatory effects on neocortical and hippocampal function. In contrast, the loss of glutamate, the primary excitatory neurotransmitter, reflects degeneration of cortical pyramidal neurons.

Abundant evidence suggests that the clinical syndrome involves failed neurotransmission at cholinergic synapses in neocortex and hippocampus (Coyle et al. 1983). This concept is based on numerous observations. First, presynaptic cholinergic markers are decreased in neocortex and hippocampus in AD, and they have been found to correlate with dementia severity (Bowen and Francis 1990; Davies and Maloney 1976). Second, basal forebrain neurons, which provide the majority of cholinergic innervation to the neocortex and hippocampus, degenerate in AD (Whitehouse et al. 1982). Third, basal forebrain lesions or pharmacological blockade of muscarinic acetylcholine receptors (mAChR) impairs learning, memory, and attention (Bartus et al. 1982; Damasio et al. 1985; Drachman 1977). Fourth, clinical trials of acetylcholinesterase (AChE) inhibitors show improved cognition and quality of life, reduced behavioral problems, and delayed institutionalization (Cummings and Cole 2002; Dooley and Lamb 2000; Knopman et al. 1996; Lamb and Goa 2001; Olin and Schneider 2002). Finally, brains from Parkinson's disease patients treated chronically with antimuscarinic drugs show increased AD neuropathology compared to brains from untreated or acutely treated patients (Perry et al. 2003).

Perturbations in specific cholinergic markers seem to occur at different stages of the disease (Mufson et al. 2003). For example, the numbers of neurons in the basal forebrain that express choline acetyltransferase (ChAT) and vesicular acetylcholine transporter (VAChT) are not altered in cases of mild cognitive impairment (MCI; a prodrome of clinically defined AD) or even in the early stages of AD (Gilmor et al. 1999). However, the numbers of basal forebrain neurons expressing $p75^{NTR}$, a low-affinity neurotrophin receptor (NTR), are significantly decreased in both AD and MCI (Mufson et al. 2002). These findings have been suggested to reflect a phenotypic alteration in cholinergic basal forebrain neurons that precedes absolute neuron loss, and they highlight the importance of developing neuroprotective strategies that could be utilized, even after symptoms emerge, to prevent or slow the degeneration of cholinergic and other neurons. There are also complex changes in cortical markers of cholinergic neurotransmission. In early stages, ChAT, the rate-limiting enzyme for

acetylcholine synthesis, is not decreased (Davis et al. 1999; DeKosky et al. 2002). As the disease progresses, however, the activity of ChAT, together with AChE (the degradative enzyme for acetylcholine), diminishes. Of interest, molecules selectively present in cholinergic nerve terminals in cortex, including ChAT, VAChT (responsible for packaging acetylcholine into synaptic vesicles), and the high-affinity choline transporter (responsible for the uptake of choline), seem to increase, suggesting compensatory changes in surviving terminals. The diversity of molecules involved in different aspects of cholinergic transmission (Figure 48–2) provides a variety of potential strategies for reducing the dysfunction of cholinergic systems in AD.

FIGURE 48–2. Molecular basis of cholinergic neurotransmission.

Acetylcholine (ACh) is synthesized in the nerve terminal cytoplasm and is incorporated into synaptic vesicles via the vesicular acetylcholine transporter (VAChT). Upon nerve impulse, cholinergic vesicles release ACh into the synaptic cleft, where the transmitter binds to pre- and postsynaptic muscarinic and nicotinic receptor subtypes. Transmission is terminated by the rapid hydrolysis of ACh by acetylcholinesterase (AChE). The degradation product choline is recycled into the terminal by the high-affinity choline transporter (CHT). This reuptake process is a key regulated and rate-limiting step in ACh synthesis. AcCoA = acetyl coenzyme A.

AChE inhibitors are currently the primary symptomatic treatment for AD. There are different types of cholinesterase enzymes, including an AChE and a butyrylcholinesterase type, both of which degrade acetylcholine. AChE is the primary enzyme expressed by neurons, and complete disruption of the gene for this enzyme in mice results in the overactivity of cholinergic systems in both brain and peripheral nervous system. Moreover, mice deficient in AChE display significant changes in the levels, cellular distribution, and function of muscarinic acetylcholine receptors, phenomena that may antagonize the potential benefit of cholinesterase inhibitors (Volpicelli-Daley et al. 2003a, 2003b). The goal of cholinesterase inhibition in humans is to prevent the degradation of acetylcholine once it is released from surviving cholinergic nerve terminals. The typical degree of AChE inhibition achievable with available drugs is only about 30% (Kuhl et al. 2000), which provides one explanation for their modest efficacy. However, because the same activity is essential for cholinergic function in the gut and in other organs receiving autonomic innervation, more complete inhibition would likely increase the side effects that already limit the dosing of cholinesterase inhibitors. In addition, cardiac and neuromuscular blockade are major concerns with more potent and irreversible drugs that inhibit acetylcholine breakdown.

Although AChE inhibitors provide an important advance, they are limited by the above considerations. The development of compounds that bind directly to cholinergic receptors is an alternative approach to enhancing cholinergic transmission. Moreover, the discovery of families of mAChR (Bonner et al. 1987; Peralta et al. 1987) and nicotinic receptor (Sargent 1993) subtypes may enable the development of selective drugs to overcome many of the side effects associated with AChE inhibitors and nonselective agonists. Receptor subtypes often have opposing actions; therefore, targeting one subtype produces more robust effects (Bymaster et al. 1998; Farber et al. 1995). Most studies have focused on mAChRs, because this receptor family has better-defined roles in central cholinergic transmission and functions, such as learning and memory (Bartus et al. 1982; Coyle et al. 1983). The nicotinic receptors also play an important role in cognition and neurodegenerative disease (Romanelli et al. 2007). Thus, selective drugs targeted at receptor subtypes offer hope for better cholinergic-based therapies for AD and other disorders involving central cholinergic systems.

The mAChR family consists of five distinct subtypes, M_1–M_5, encoded by different genes and all expressed in the brain. The M_1, M_2, and M_4 receptors are the most abundant subtypes. Their precise roles in central cholinergic function and their potential for AD treatments remain uncertain (Levey 1996), but several lines of evidence suggest that M_1 may be a key target. M_1 is the most abundant receptor in the cortex and hippocampus; it is postsynaptic on pyramidal neurons and plays an important role in enhancing glutamatergic transmission via NMDA receptors (Marino et al. 1998). M_1 also activates protein kinase pathways involved in the long-term changes in gene expression that underlie learning and memory (Berkeley et al. 2001). There is some loss of M_1 receptor protein and high-affinity states involving coupling to G proteins (Flynn et al. 1991, 1995). M_2 is the primary autoreceptor on cholinergic terminals in cortical structures, and it is also present on inhibitory interneurons. Loss of M_2 receptors in AD probably involves both neuronal populations. M_4, the most abundant receptor in the striatum, is a presynaptic heteroreceptor on commissural projections in cortex, suggesting that it is involved in the regulation of excitatory associational connections. Of interest, this subtype is increased in AD.

Subtype-selective agonists and antagonists have been difficult to develop, but they remain promising. One of the first relatively selective M_1 agonists, xanomeline, showed significant clinical efficacy in a double-blind multicenter study (Bodick et al. 1997). Some of the most remarkable benefits were in the reduction of agitation, delusions, and hallucinations, providing evidence that the cholinergic system plays an important role in behavior as well as in cognition. Subsequent studies of cholinesterase inhibitors have reinforced this idea (Cummings and Cole 2002) and have provided a rationale for long-term treatment and use of these agents in later stages of AD. In addition to their potential benefit in ameliorating symptoms, direct-acting muscarinic receptor agonists may also alter the course of the

disease. Several preclinical studies have established distinct roles of muscarinic receptor subtypes in regulating amyloidogenesis, and an M_1 muscarinic agonist reduced both amyloid plaque and neurofibrillary tangle pathology in a transgenic mouse model of AD (Caccamo et al. 2006). In human studies, M_1 agonist treatment reduced cerebrospinal fluid (CSF) amyloid levels (Hock et al. 2003). In addition, postmortem analysis of Lewy body dementia cases treated with cholinesterase inhibitors showed significantly less amyloid pathology than cases examined prior to the advent of these drugs (Ballard et al. 2007). While these studies suggest that cholinergic treatment has the potential to be disease modifying, the therapeutic potential of drugs selective for cholinergic receptor subtypes remains to be determined.

Neurochemical alterations in serotonin, norepinephrine, and glutamate also have important therapeutic implications for AD. Serotonin plays a key role in mood and anxiety disorders, which commonly coexist with dementia in AD. Selective serotonin reuptake inhibitors are frequently used for these patients and have demonstrated efficacy. There is a loss of noradrenergic neurons in the locus coeruleus in AD, although the significance of this change and its implications for therapeutic intervention are only beginning to be systematically investigated. Preclinical studies have suggested that noradrenergic neurotransmission may have a role in disease modification. For example, locus coeruleus degeneration exacerbated amyloid pathology, behavioral deficits, and neuron loss in a transgenic mouse model of AD, suggesting that loss of noradrenergic neurotransmission may be a contributing factor in the development or progression of AD (Heneka et al. 2006). Drugs that modulate glutamatergic transmission also have potential utility for the cognitive and behavioral symptoms of AD. In addition, since excitotoxicity may play some role in the neurodegenerative process, such drugs could potentially be neuroprotective. Ampakines, a class of drugs that modulate amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) subtypes of glutamate receptors, are under development. Memantine, a noncompetitive NMDA antagonist, is now approved for the treatment of AD in the United States. Although clinical trials of high-affinity NMDA antagonists have been hindered by serious side effects, memantine seems to be well tolerated. Recent clinical trials indicate a significant benefit of this drug in AD patients, particularly with respect to language and memory domains (Peskind et al. 2006; Pomara et al. 2007).

RISK FACTORS AND CLUES TO THE BIOLOGY OF ALZHEIMER'S DISEASE

Aging is the biggest risk factor for AD, and the prevalence of AD doubles about every 5 years after age 65 years, increasing to about 40% by age 85 years. This relationship has contributed to speculations that AD is simply accelerated aging (rather than a disease) and that everyone would develop AD if they lived long enough. However, the risk may actually decline after age 90 years (Lautenschlager et al. 1996), indicating that AD is not an inevitable result of aging. Because age alone is insufficient to cause the disease, other risk factors must therefore interact with the aging process (Table 48–1). Of the many factors that have been examined, retrospective studies indicate that individuals with severe traumatic brain injury have a higher-than-expected incidence of AD pathology (Jellinger et al. 2001). Head injury also seems to interact with genetic predisposition (ApoE ε4) to decrease the age at AD onset (Mayeux et al. 1995; Schofield et al. 1997). Down syndrome is another well-established risk factor. Virtually all Down syndrome patients who are older than 40 years of age exhibit the hallmark neuropathology of AD (Karlinsky 1986). However, clinically evident AD is less common. There is also an increased risk for mothers of children with Down syndrome (Schupf et al. 2001).

TABLE 48–1. Risk factors for developing Alzheimer's disease (AD)

Category	Factor	Influence on AD risk
Life events	Aging	Risk increases with increasing age
	Early-life linguistic ability	Decreases risk
	Traumatic brain injury	Increases risk

Category	Factor	Influence on AD risk
Genetics	Down syndrome	Greatly increases risk
	ApoE ε4	Increases risk
Sex	Female vs. male	Females have increased risk
	Estrogen replacement	Sustained estrogen replacement may lower risk
Diet/medication	Vitamin/nutrient supplementation	Vitamins C and E may be protective
	Nonsteroidal anti-inflammatory drug use	Decreases risk
	Statin use	Decreases risk
Cardiovascular risk factors	Hypercholesterolemia	Increases risk
	Hypertension	Increases risk
	Elevated plasma homocysteine	Increases risk
	Diabetes mellitus	Increases risk

Several studies suggest that education (D. A. Evans et al. 1997; Katzman 1993; Stern et al. 1994) and early cognitive and linguistic abilities (Snowdon et al. 1996; Whalley et al. 2000) correlate with decreased risk for AD. In many studies, a higher level of education is associated with a lower risk of developing AD (D. A. Evans et al. 1997; Katzman 1993; Stern et al. 1994). Participation in other activities that require cognitive ability is also associated with a lower risk of AD (Wilson et al. 2002). One possible explanation is that people who are more intelligent and healthy have a higher "cerebral reserve" and thus do not manifest signs of dementia until more brain tissue is damaged. In a longitudinal study of AD in a group of nuns, linguistic ability in early life strongly predicted cognitive abilities in old age (Snowdon et al. 1996). In addition, neuropathological analysis has documented significant correlations between low idea density in early-life autobiographies and neuropathological signs of AD (Riley et al. 2005). Similarly, in a Scottish study, lower performance on childhood school tests was associated with increased late-life dementia (Whalley et al. 2000). Despite obvious limitations in these types of correlational studies, the strength of the associations raises the intriguing possibility that developmental mechanisms or early education may play a role in the development of AD in late life.

Epidemiological studies indicate that AD is more common in women, and initial reports suggested that postmenopausal estrogen replacement is associated with a lower incidence of AD. There is experimental evidence that estrogen may modify the production of Aβ peptide (Xu et al. 1998), linking the epidemiological data with a potential biological mechanism. Additional studies of hormone replacement therapy have produced conflicting data. In the Women's Health Initiative Memory Study (WHIMS), both estrogen plus progestin and estrogen therapy alone were found to be associated with an increased risk of developing dementia (Shumaker et al. 2003, 2004). However, the Cache County Study found that hormone replacement therapy is associated with a lower risk of late-onset AD in a manner dependent on the duration of exposure. In this study, women taking hormone replacement therapy for more than 10 years showed the greatest reduction of AD risk (Zandi et al. 2002). The observed gender bias may reflect biological factors underlying disease susceptibility or, alternatively, the greater longevity of females (Hebert et al. 2001). Other gender-specific factors may exist, however. For example, the offspring of a father with AD have a 1.4-fold greater risk than if the mother was affected (Lautenschlager et al. 1996). Despite an increasing understanding of the interaction between hormones and the risk of dementia, the precise role of gender in AD pathogenesis remains to

be clarified.

Epidemiological studies have revealed patterns of medication use associated with altered risk of AD, including exposure to nonsteroidal anti-inflammatory drugs (NSAIDs) and 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins). The magnitude of the reduced risk associated with NSAIDs, estrogen, or statins is similar, ranging from ~30% to 80%. As with any epidemiological study, a variety of biases are possible, and results do not imply a causal relationship. Nevertheless, several epidemiological investigations, including one large prospective population-based study, have found the relative risk of AD to be lower with long-term use of NSAIDs (in t' Veld et al. 2001). Thus far, only two small prospective clinical trials of NSAIDs have indicated a protective effect in AD. Notably, all trials involving selective cyclo-oxygenase-2 (COX-2) inhibitors have been negative, a finding that may shed light on the biological mechanism by which certain nonselective anti-inflammatory agents exert their protective effect (Aisen et al. 2003; McGeer and McGeer 2007).

There is accumulating evidence that some NSAIDs modulate the activity of the γ-secretase enzyme independently of their effect on cyclo-oxygenase enzymes, and Phase II clinical trials have shown that the Aβ42-lowering drug R-flurbiprofen may have cognitive and behavioral benefits in AD. It is unclear whether NSAIDs will ultimately prove to be beneficial in AD, but because these medications have serious potential side effects, the evidence to date does not warrant recommendations for use as a primary treatment for AD. Epidemiological studies have also shown that statins are associated with a significantly lower relative risk of AD (Jick et al. 2000; Rockwood et al. 2002; Wolozin et al. 2000) and that the association seems specific, compared with the use of other lipid-lowering agents and cardiovascular drugs. Given that hypercholesterolemia is a potential risk factor for developing AD (Kivipelto et al. 2001; Notkola et al. 1998), the data linking statin use and decreased risk of AD strengthen the biological relationship between cholesterol homeostasis and AD. The results of additional research, including ongoing multicenter clinical trials, will ultimately determine the role for statins in the growing armamentarium of AD therapies. Taken together, these associations provide potential insights into the biology of AD. Specifically, they implicate hormones, inflammation, and cholesterol as relevant factors for further study in the pathogenesis of the disease.

It has been postulated that several lifestyle factors, including dietary habits, physical activity, and leisure activities (Scarmeas et al. 2001), play a role in the development of AD. Dietary intake of several vitamins and nutrients has been studied. Subclinical deficiencies of vitamin B_6, vitamin B_{12}, and folate are associated with poorer cognitive function in the elderly, and AD patients tend to have lower levels of these vitamins (Clarke et al. 1998; H. X. Wang et al. 2001). These vitamins are essential cofactors in the generation of donor methyl groups, which in turn are necessary for the biosynthesis of numerous neural components, such as neurotransmitters and myelin. Therefore, mild defects in the methyl donor pathway might have subtle effects on neuronal function and viability. Alternatively (or additively), the deleterious effects of B vitamin or folate deficiency may be mediated by elevated homocysteine, a metabolite of the methyl donor pathway. Homocysteine causes vascular damage and has been linked to ischemic changes in the brain, as well as in other organs. Beginning several years before diagnosis, patients with AD have elevated homocysteine levels (Seshadri et al. 2002), regardless of vitamin B_{12}/folate status. This observation adds to the growing connection between vascular disease and AD (Kivipelto et al. 2001). Vitamin D deficiency, a common disorder among the elderly, has been recently linked with poor cognitive performance in participants of a study of memory and aging (Wilkins et al. 2006). The antioxidant vitamins C and E have been associated with reduced risk of AD (Engelhart et al. 2002). Despite an initial finding that vitamin E slows disease progression in patients with AD (Sano et al. 1997), another study demonstrated that vitamin E had no apparent effect on progression from MCI to AD, even among high-risk subjects (ApoE ε4 positive) (Petersen et al. 2005). However, major differences in the study populations may have influenced the outcomes. AD has also been linked to dietary fat intake—namely, with higher levels of total and saturated fat and cholesterol and with lower levels of fish oils, which contain polyunsaturated fats.

While it is not clear exactly how these dietary factors impact the development and progression of AD, if the associations are confirmed in clinical trials, which are currently under way, specific nutritional interventions may be warranted as a means of preventing or slowing the onset of disease.

The effects of ethanol and smoking remain unclear. Heavy ethanol use produces a characteristic dementia syndrome that shares some features with AD. Of interest, several studies have found that moderate consumption of red wine was associated with a decreased risk of AD (Luchsinger et al. 2004; Orgogozo et al. 1997). Moderate ethanol intake has been linked to improved cardiovascular health, which may account for this effect. Conflicting evidence exists regarding the effects of smoking. Some studies have found an increased incidence of AD in smokers, which could be caused by the well-established deleterious effects of smoking on cardiovascular health. Other studies have observed that smokers have a lower risk of AD. Although surprising, this latter observation might be attributable to the stimulatory effects of nicotine at nicotinic acetylcholine receptors.

In addition, decreased leisure activity in midlife is a risk factor for AD (Scarmeas et al. 2001). Although people who remain active may be enhancing their cerebral reserve, it is also possible that decreased leisure activity is an early sign of subclinical cognitive impairment.

GENETICS

AD is a complex genetic disease. Multiple genes are associated with the disease, with mutations in some genes linked to fully penetrant cases with autosomal dominant inheritance and polymorphisms in other genes linked to disease risk. To date, four genes—*APP, PSEN1, PSEN2,* and *APOE*—have been consistently linked to AD in studies around the world (Blacker and Tanzi 1998; Selkoe and Podlisny 2002). Many other genes have been associated with AD in only a few studies and/or remain controversial, and these genes will not be discussed here unless otherwise specified. It is clear that several other genes with strong links to AD remain to be identified. The diversity of genes and other factors result in two major presentations of illness: familial and sporadic.

Less than 5% of all cases of AD are familial—mostly with an early onset (i.e., younger than 65 years)—and they seem to follow an autosomal dominant mode of inheritance. In these families, mutations in three distinct genes—*APP* on chromosome 21, *PSEN1* on chromosome 14, and *PSEN2* on chromosome 1—have been linked to the affected individuals. Although important for understanding the biology of AD, *APP* mutations are extremely rare. *PSEN1* mutations account for the majority of the familial cases with early-onset disease. Although *APP* and *PSEN1* mutations are linked exclusively to families with early onset, some families with *PSEN2* mutations exhibit symptom onset in their late 60s or 70s, suggesting that the pathogenic mechanisms are less severe. *PSEN2* mutations are mostly associated with descendants of Volga Germans. Collectively, *APP, PSEN1,* and *PSEN2* mutations account for most families with autosomal dominant AD, but for at least 30% of familial cases, other responsible genes remain to be elucidated (Liddell et al. 2001).

The vast majority of AD cases are termed sporadic, in that they do not have a definite familial clustering or linkage to a known disease-causing mutation. However, in many of these cases, careful family histories suggest that relatives have been affected, indicating contributions from genetic factors. For example, about one-third of sporadic AD cases are associated with a positive family history (Rosen et al. 2007). Only one gene, *APOE,* has been reproducibly associated with AD risk in virtually all populations and studies. The *APOE* genotype is not causative (as in the case of the autosomal dominant *APP, PSEN1,* and *PSEN2* mutations), but inheritance of different alleles is significantly associated with a modified risk of AD. *APOE* exists as three allelic variants (ε2, ε3, and ε4), and inheritance of the *APOE4* allele confers a greater risk of AD. Individuals who are homozygous for *APOE4* have a substantially greater risk of developing AD than individuals with no *APOE4* alleles (*APOE* 2/2, 2/3, or 3/3 genotype), and individuals with a single *APOE4* allele (*APOE* 2/4 or 3/4) have an intermediate risk (Chartier-Harlin et al. 1994; Corder et al. 1993; Saunders et al. 1993). The age at

disease onset is lower among AD patients who possess an *APOE4* allele (Corder et al. 1993; Tsai et al. 1994). These genetic associations strongly suggest that the *APOE* genotype plays an important contributing role in the development of sporadic AD.

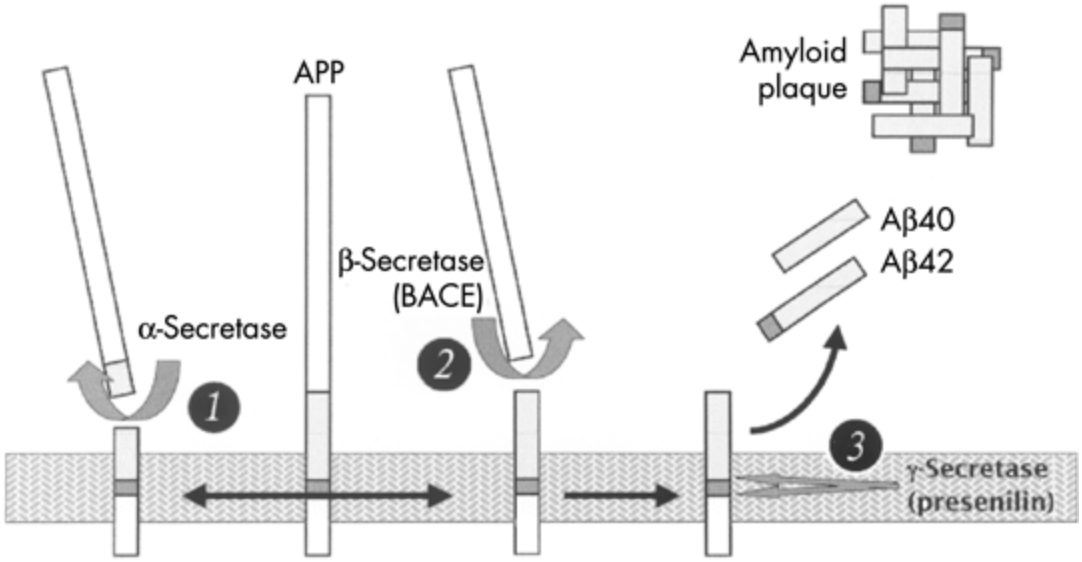
In addition to *APOE4,* there are likely to be many other genes that contribute to AD susceptibility, albeit with lesser influence on risk. It has been difficult to identify these other genes because of the smaller degree of risk associated with them. However, numerous genetic association studies have examined many other candidate genes for the risk of sporadic or late-onset AD, and some positive associations have been reported. Polymorphisms in the *SORL1* gene, which encodes the neuronal receptor LR11/sorLA, have recently been associated with AD in multiple populations (J. H. Lee et al. 2007; Rogaeva et al. 2007). Given the strong biological evidence for the role of this receptor in AD pathogenesis (Andersen et al. 2005; Offe et al. 2006; Scherzer et al. 2004), further research is warranted to elucidate the pathogenic mechanisms of genetic variants of *SORL1.* Interest in genes with potential biological plausibility has increased, particularly those linked to mechanisms such as inflammation (interleukin 1 [IL-1] and α-macroglobulin) and amyloidogenesis (nicastrin, insulin-degrading enzyme, and neprilysin). However, almost all of these studies have been underpowered, and the results have not been reliably confirmed in multiple studies using large independent populations. Nonetheless, abundant evidence suggests that several other genes contribute to the risk of sporadic AD. Undoubtedly, additional genetic factors will be identified in the near future, providing new clues to the pathogenesis of the disease. As knowledge of genetic associations in AD continues to grow, it will be important to integrate this information in a systematic manner. A recent meta-analysis has catalogued all published studies of genetic associations in AD and has made this information publicly available in a continuously updated online forum (Bertram et al. 2007). Coordinated efforts such as this will undoubtedly catalyze rapid progress in the understanding of this disease as well as treatment strategies.

THEORIES OF ETIOPATHOGENESIS

The cause of most cases of AD remains unknown. As discussed above, autosomal dominant single-gene mutations in *APP, PSEN1,* and *PSEN2* are sufficient to cause disease in a small percentage of cases, but even in these familial cases, the relationship between mutant genes and neurodegeneration is not completely understood. Postmortem observations in brains with AD, including changes in neurotransmitter systems, accumulation of amyloid plaques, intraneuronal neurofibrillary tangles, inflammatory changes, increased oxidative stress, mitochondrial dysfunction, and reactivation of cell cycle–related gene products, have spawned numerous theories regarding the etiopathogenesis of AD. It is likely that many of these observations reflect different aspects of disease initiation and progression, and one of the key goals in AD research is to develop a unifying theory that accurately identifies the triggering event(s) and explains the relationship between apparently distinct elements of disease biology and neuropathology. Achievement of this daunting task will provide a foundation for developing rational therapeutic approaches for treating patients with AD at different stages of illness.

Although a complete discussion of all of the theories of the pathogenesis of AD is beyond the scope of this chapter, the amyloid cascade hypothesis has gained increasing support in recent years and merits more detailed discussion. It should be understood that whereas this is the theory currently favored by many investigators, the hypothesis is not proven. Indeed, evolution and refinement of the hypothesis are quite likely. Nevertheless, it does have considerable value in establishing a rationale for developing and testing potential therapies. In addition to the amyloid hypothesis, other theories have particular relevance for current clinical practice. The involvement of cholinergic systems was discussed earlier, and the roles of inflammation and oxidative injury in the pathogenesis of AD are discussed briefly below.

Amyloid Cascade Hypothesis



Since its identification as the primary component of senile plaques in 1984, the Aβ peptide and its precursor molecule, amyloid-β precursor protein (APP), have been the targets of intense research interest. The importance of these molecules in the pathogenesis of AD is supported by neuropathological observations and a variety of experimental data. As noted previously, amyloid-containing senile plaques are invariably present in the brains of patients with AD. More recently, characterization of genes associated with early-onset familial AD (*APP, PSEN1,* and *PSEN2*) and late-onset sporadic AD (*APOE*) has strengthened the notion that abnormal metabolism of Aβ plays a central role in disease pathogenesis.

The amyloid hypothesis of AD proposes that amyloid production and accumulation play the central role in initiating a cascade of events that leads to cellular dysfunction, neuron loss, and eventual clinical disease manifestations. Downstream effects may involve cytoskeletal dysfunction, inflammation, oxidative injury, neuronal apoptosis, and other mechanisms that result in neurodegeneration, but a critical tenet of the hypothesis is that abnormal Aβ metabolism represents the principal triggering event. An important corollary to this hypothesis is that interventions that reduce the production and deposition of amyloid may provide an effective means of ameliorating symptoms, halting progression, and possibly preventing disease. The amyloid cascade hypothesis has become widely accepted, and most current efforts to develop new therapies for AD directly or indirectly target this mechanism (Hardy and Selkoe 2002).

Mechanisms of Amyloidogenesis

Production of Aβ from APP is regulated by three enzymes (α-, β-, and γ-secretases) (Figure 48–3). Initial cleavage by α-secretase precludes A production by cleaving APP within the Aβ domain. Alternatively, cleavage by β-secretase, followed by γ-secretase activity, produces Aβ. Although the predominant Aβ species is a peptide that is 40 amino acids in length (Aβ40), a slightly longer form (42 amino acids [Aβ42]) seems to have particular pathogenic significance. Because of its biophysical properties, Aβ42 is substantially more fibrillogenic than Aβ40 (Barrow and Zagorski 1991; Burdick et al. 1992; Knauer et al. 1992), and it is believed that extracellular aggregation of Aβ42 provides a nidus on which additional Aβ deposition and plaque formation can occur. Pathological examination of brains with AD suggests that Aβ42 is present at early stages of amyloid deposition in diffuse plaques, whereas Aβ40 is prominent in mature neuritic plaques (Iwatsubo et al. 1994). The physiological significance of Aβ42 was highlighted by the recognition that pathogenic mutations in *PSEN1* and *PSEN2* invariably increase the production of Aβ42, relative to Aβ40 (Borchelt et al. 1996; Citron et al. 1997; Duff et al. 1996; Scheuner et al. 1996; Tomita et al. 1997). To date, more than 125 distinct mutations in *PSEN1* and *PSEN2* have been reported in human pedigrees associated with autosomal dominant familial AD. All of these mutations enhance the production of the longer form of the Aβ peptide, suggesting that overproduction of Aβ42 plays an important role in the pathogenesis of aggressive early-onset forms of AD.

FIGURE 48–3. Proteolytic cleavage of amyloid precursor protein (APP) and amyloidogenesis.

The APP molecule is metabolized via alternate pathways with distinct cleavages. A nonamyloidogenic pathway involves an α-secretase cleavage *(1)* within the Aβ peptide sequence *(lightly shaded),* shedding an N-terminal ectodomain. Degradation of the membrane-bound C-terminus does not produce Aβ, because part of the peptide sequence has been cleaved. In contrast, Aβ is produced via the amyloidogenic pathway involving sequential cleavages by β-secretase *(2)* and γ-secretase *(3).* Presenilin is a necessary component for γ-secretase activity. The final γ-secretase cleavage releases Aβ peptides of predominantly 40–42 amino acids. The longer 42-residue peptide is more toxic and hydrophobic, and it seeds aggregation into extracellular deposits of amyloid plaques. BACE = beta-site APP cleaving enzyme.

Intense research efforts have yielded rapid advances in our understanding of the mechanisms mediating Aβ production. The enzyme responsible for β-secretase cleavage of APP has been identified (Hussain et al. 1999; Vassar et al. 1999; Yan et al. 1999). Beta-site APP cleaving enzyme (BACE) represents the primary β-secretase activity in brain tissue, and initial results from BACE knockout mice suggested that disruption of BACE expression could drastically reduce brain Aβ production without causing significant developmental problems or toxicity in adult animals (Cai et al. 2001; Luo et al. 2001; Roberds et al. 2001). However, a recent study has documented that deletion of BACE in mice results in hypomyelination of peripheral nerves (Willem et al. 2006), raising concerns about potential side effects of BACE inhibitors. Nevertheless, pharmacological inhibitors of BACE are under active development and may represent a viable therapeutic approach to AD. It is important to note that BACE is a member of a conserved family of membrane-bound aspartic proteases of unknown functions (Lin et al. 2000; Turner et al. 2002). The existence of these related enzymes poses uncertain risks, and the potential usefulness of β-secretase inhibitors will depend greatly on the ability to design pharmacological agents capable of specifically inhibiting brain β-secretase activity without affecting the biological activity of related enzymes.

The discovery of γ-secretase as a complex of multiple proteins, including presenilin, represents a critical advance in the understanding of APP processing and has presented an additional avenue of therapeutic intervention for AD (Edbauer et al. 2003; Kimberly et al. 2003). As discussed above, pathogenic mutations in *PSEN1* and *PSEN2* alter γ-secretase cleavage of APP, resulting in enhanced production of the longer (42-amino-acid) Aβ. The precise mechanism by which mutations alter APP cleavage remains unclear, but presenilin appears to be involved in the active site of the enzyme.

Pivotal observations in *PSEN1* knockout mice revealed dramatic reduction in Aβ production (De Strooper et al. 1998). Subsequently, it was recognized that two highly conserved aspartate residues in PS1 and PS2 are critical for γ-secretase activity, suggesting the possibility that presenilins might possess intrinsic protease activity (Wolfe et al. 1999). In addition, transition-state enzyme inhibitors modeled on the γ-secretase active site seem to physically interact with presenilin (Esler et al. 2000; Y. M. Li et al. 2000; Shearman et al. 2000). The structure of presenilins, which contain multiple membrane-spanning domains, is distinctly unusual for aspartyl proteases. The γ-secretase complex is tightly regulated and appears to require coordinated expression for normal maturation and stability of the components (Periz and Fortini 2004).

Presenilins appear to play an essential role in the final cleavage step that produces Aβ, presenting another potential target for new therapeutic agents. Unlike BACE, however, loss of *PSEN1* has clearly detrimental effects in animal models. Targeted gene disruption and loss of *PSEN1* in knockout mice result in a late embryonic lethal phenotype associated with severe developmental defects (Shen et al. 1997). These effects arise from an unexpected link between γ-secretase activity and Notch, a receptor that plays a critical role in cell fate decisions during development. In addition to APP, presenilin and γ-secretase regulate the proteolytic processing of a growing list of important molecules, including Notch, erb4, the epidermal growth factor (EGF) receptor, the $p75^{NTR}$ low-affinity neurotrophin receptor, and many others (De Strooper et al. 1999; Jung et al. 2003; H. J. Lee et al. 2002; Struhl and Greenwald 1999; Weihofen et al. 2002; Ye et al. 1999). These additional functions present a serious challenge for developing γ-secretase inhibitors as potential therapeutic agents for AD. Nevertheless, γ-secretase inhibitors are still undergoing clinical trials, and improved understanding of presenilin function may reveal effective approaches for disrupting γ-secretase activity in a brain- and APP-specific manner.

Mechanisms of Amyloid-Beta Peptide Clearance

Aβ production from APP has been studied more intensively than perhaps any other process in protein biochemistry. The other half of the equation, the clearance of Aβ, has received less attention but may be equally important in regulating Aβ. The mechanisms responsible for amyloid degradation and clearance are not fully understood, but several metallopeptidases, including the insulin-degrading enzyme (IDE), are known to have Aβ-degrading activity (Kurochkin 2001; Qiu et al. 1998). Of interest, the *IDE* gene is present on chromosome 10q, near a region of linkage with late-onset AD. While results from genetic analyses have varied (Abraham et al. 2001; Bertram et al. 2000), current findings support both genetic and functional links between IDE and AD pathogenesis (Bertram et al. 2007; Kim et al. 2007). Administration of thiorphan, a potent inhibitor of the neprilysin family of zinc metalloproteinases, increased Aβ deposition in rat brain (Carson and Turner 2002; Iwata et al. 2000). Abnormalities in endosomal–lysosomal function may also be relevant to Aβ-degrading activity in neurons. These changes are among the earliest neuropathological changes present in AD brains, visible in presymptomatic individuals at high risk of developing AD, and they appear to be fundamentally linked to APP expression (Cataldo et al. 2000, 2003; Troncoso et al. 1998). Although genetic evidence from familial AD pedigrees associated with *APP, PSEN1,* and *PSEN2* mutations identifies abnormal production of Aβ as a pivotal mechanism in disease pathogenesis, abnormal degradation and clearance of amyloid may be an equally important mechanism in sporadic cases of AD.

As noted above, the *APOE* gene exists in three different allelic forms (ε2, ε3, and ε4), and the ε4 allele has been shown to be an important risk factor for sporadic late-onset AD. Studies of this gene have revealed a number of potential links to amyloidogenesis. The apoE protein is present in amyloid deposits, and plaque burden is increased in individuals with AD possessing ε4 alleles (Gearing et al. 1995; Rebeck et al. 1993; Schmechel et al. 1993). One possible explanation for this may be that the apoE4 protein isoform enhances the deposition of fibrillar Aβ peptides (Castano et al. 1995; K. C.

Evans et al. 1995; Wisniewski et al. 1994). Interaction between Aβ and apoE4 may promote extracellular amyloid deposition and trigger the cascade of events leading to the development of AD (Wisniewski et al. 1994). An alternative means by which apoE may influence amyloidogenesis involves a brain apoE receptor called low-density lipoprotein (LDL) receptor–related protein (LRP) (Kounnas et al. 1995). This receptor mediates internalization of apoE-containing lipid particles, and through its interaction with α_2-macroglobulin, LRP can also mediate clearance of Aβ (Kang et al. 2000; Shibata et al. 2000). The LDL- and sortilin-related receptor LR11/SorLA has recently been shown to modulate amyloidogenesis, presumably by regulating APP traffic through endosomal compartments (Andersen et al. 2005; Offe et al. 2006). Since LR11/SorLA is also an apoE receptor, this represents yet another possible mechanism by which apoE may influence AD development and progression. As noted above, variants in *SORL1,* the gene that encodes LR11/SorLA, are associated with late-onset AD in multiple populations (J. H. Lee et al. 2007; Rogaeva et al. 2007). Further investigation is warranted to fully determine the cell biological significance of this receptor in normal neuronal function and disease states, but its identification represents a major advance in understanding the basis of late-onset AD, the most common form of the illness.

The appearance of dense deposits of amyloid in senile plaques produces the impression that they are static lesions. However, evidence from transgenic mouse models of AD suggests that extracellular amyloid may be much more dynamic than previously believed. Examination of plaque formation in live animals indicates that plaques can form rapidly, disrupting the architecture of dendrites in their vicinity. Remarkably, administration of anti-Aβ antibodies to plaque-forming mice results in rapid clearance of amyloid plaques and restoration of normal dendritic morphology (Lombardo et al. 2003; Spires et al. 2005). In addition, vaccination to induce production of anti-Aβ antibodies has shown a dramatic ability to prevent or reverse the accumulation of amyloid plaques in animal models (Morgan et al. 2000). These observations suggest that the induction of immunity to Aβ may be a viable treatment for AD. The first clinical trial employing this approach was halted because of safety concerns and the development of encephalitis in some patients receiving the Aβ vaccine, but the notion of promoting amyloid clearance as a potential treatment strategy remains viable. Of particular note, participants in the original trial who were good antibody responders had better outcomes than placebo-treated patients in cognitive as well as pathological assessments (Fox et al. 2005; Gilman et al. 2005). Furthermore, cognitive improvement was correlated with antibody titer, suggesting a direct relationship between anti-Aβ immune response and favorable clinical outcome. Several humanized anti-Aβ monoclonal antibodies are currently being tested, and vaccine and passive immunization strategies designed to minimize adverse side effects are under way in early phases of human clinical trials.

Inflammation and Alzheimer's Disease

Inflammation is a key component of AD (Eikelenboom et al. 2000; McGeer and McGeer 2001a; McGeer et al. 2006). In fact, the presence of an inflammatory response is a key feature that distinguishes the pathological neuritic plaque from the benign diffuse plaque. Neuritic plaques are surrounded by activated astrocytes and microglia, the resident immune cells of the central nervous system. Activated complement, including membrane attack complexes, is prominent on damaged neurons and dystrophic neurites. A classical antibody-mediated pathway or an alternative antibody-independent pathway can activate complement, but brains from patients with AD do not show increased antibodies or T cells, indicating that a specific immune response is not responsible for complement activation. The most likely trigger for complement activation in AD is Aγ itself. Several inflammatory proteins are also elevated in AD. These include C-reactive protein, amyloid P, α_2-macroglobulin, intercellular adhesion molecule–1 (ICAM-1), and proinflammatory cytokines, such as IL-1, interleukin 6 (IL-6), and tumor necrosis factor–α (TNF-α). Many of these proteins can influence APP expression and processing, and many associate with Aβ in plaques. Genetic polymorphisms in proinflammatory genes, including IL-1, TNF-α, and α_2-macroglobulin, have been associated (albeit inconsistently) with an increased

likelihood of developing AD or an earlier age at disease onset (McGeer and McGeer 2001b).

The role of anti-inflammatory agents in the treatment of AD remains unclear. In numerous epidemiological studies, the use of NSAIDs was suggested to prevent or delay AD (in t' Veld et al. 2001; Stewart et al. 1997). However, randomized trials with NSAIDs (as well as with other anti-inflammatory agents, such as COX-2 inhibitors and steroids) have shown little benefit. Because the strongest association of NSAIDs in epidemiological studies is with drug exposure that is at least 2–3 years before disease onset, it is possible that anti-inflammatory agents may have a protective role only at earlier preclinical stages of AD. In addition, the lack of positive outcomes in prospective anti-inflammatory drug trials may also reflect inappropriate choice of drugs or suboptimal dosages. Numerous biochemical and transgenic mouse model studies now support the hypothesis that some, but not all, NSAIDs lower Aβ42 by directly modulating the activity of γ-secretase in a manner independent of their action on COX-1 and COX-2 (Eriksen et al. 2003; Weggen et al. 2001, 2003). Considering this, it may be important to consider alternative mechanisms other than COX inhibition (such as γ-secretase regulation) when selecting anti-inflammatory drugs for human AD trials.

Aging, Oxidative Injury, and Mitochondrial Dysfunction

Oxidative injury is caused by the reaction of free radicals with cellular components. The major source of oxygen-containing free radicals is incomplete reduction of oxygen by the mitochondrial electron transport chain. Oxygen free radicals are highly reactive and can damage cellular lipids, proteins, and DNA. The brain is particularly susceptible to oxidative injury for several reasons: high oxygen consumption; increased levels of transition metals, which act as catalysts for free radical generation; low levels of endogenous antioxidants; and an abundance of polyunsaturated lipids, which are more prone to free radical modification.

Extensive evidence supports a role for oxidative damage in AD. Numerous studies have shown higher levels of oxidized lipids, proteins, and DNA in brains from AD patients. Of significance, oxidative damage is highest in brain areas that are most heavily affected in AD (e.g., neocortex and hippocampus) and lowest in areas that are spared (e.g., cerebellum) (Praticò 2002). Neurofibrillary tangles and amyloid plaques show signs of oxidative injury. Oxidative damage may play a central role in the formation of these pathological hallmarks by promoting protein cross-linking and aggregation. The cytotoxic effect of Aβ is mediated by reactive oxygen species; antioxidants can attenuate amyloid-induced neuronal cell death in vitro (Markesbery 1999). Oxidative injury also increases with normal aging, providing a possible explanation for the association between aging and AD.

Is oxidative stress a key player in disease etiology, or is it merely a secondary effect of neuronal damage? Increasing evidence implies that oxidative damage may be an early event (Beal 2005). In AD brains, healthy neurons in vulnerable brain areas have increased amounts of 8-hydroxy-guanosine (8-OHG), a marker of recent oxidative damage (Smith et al. 2000). In contrast, neurons with neurofibrillary tangles have low levels of 8-OHG, implying that oxidative injury precedes tangle formation. In transgenic mouse models of AD, mice expressing a mutant form of *APP* show increased lipid peroxidation months before amyloid deposits are first detected (Praticò et al. 2001). Strikingly, loss of one allele of the manganese superoxide dismutase (*MnSOD*) gene significantly increases amyloid plaque deposition in APP transgenic mice (F. Li et al. 2004). Potential sources of early oxidative stress include mitochondrial dysfunction and changes in cytoplasmic transition metals like copper and zinc.

The role of oxidative stress in AD has implications for both disease diagnosis and treatment. Increased levels of oxidized lipid metabolites are detectable in the CSF, serum, and urine of patients with AD. Levels of one metabolite, an isomer of prostaglandin F2, are elevated in the CSF of patients with mild cognitive impairment, a condition that progresses to AD in 50% of cases (Praticò et al. 2002). Thus, detection of increased oxidative stress may be useful for the diagnosis of existing or future AD.

Antioxidants may also play an important role in AD therapy. Observations from the Cache County Study Group have indicated reduced risk of AD among participants taking vitamin C and E supplements, and better cognitive performance was noted among participants who reported a diet rich in antioxidants (Wengreen et al. 2007; Zandi et al. 2004). However, data from controlled clinical trials have been mixed. The antioxidants vitamin E and selegiline have been shown to slow disease progression by 6–12 months in patients with moderate AD (Sano et al. 1997). However, another recent trial found no benefit from vitamin E in preventing the development of AD in patients with mild cognitive impairment (Petersen et al. 2005). Additional trials with more potent antioxidants are also in progress.

FUTURE DIRECTIONS

Although much progress has been made toward understanding the biological basis of AD, it is clear that further advances are required to identify individuals at risk and develop effective treatments to prevent or reverse disease progression. As is the case with other neurodegenerative diseases, early detection is paramount to the success of treatment of AD. In the past 5 years, exciting progress has been made in the development of molecular probes and imaging techniques to monitor the development and progression of AD neuropathology in living human subjects. As these technologies improve, they will permit earlier and more accurate diagnosis of AD and enable scientists and clinicians to evaluate the efficacy of treatments. The identification of biomarkers specific for AD will aid tremendously in the development of screening tools that can be used efficiently to detect the early stages of AD in the general population. It is also becoming clear that AD has a substantial genetic component (distinct from the small percentage of "familial" AD cases that are attributable to known genes), and the elucidation of new AD-associated genes will certainly improve the ability of the medical community to counsel and treat those at increased risk of developing the disease.

The treatments for AD are evolving from a strategy of neurotransmitter replacement (via inhibition of AChE) to therapies that target discrete molecular events in the disease pathogenesis. Ongoing research in Aβ immunotherapy and clearance, neuroprotective and antioxidant agents, and compounds designed to modulate endogenous signaling pathways promises to revolutionize the way AD is approached as an illness. Consequently, it can be expected that the results of AD therapies will soon move beyond modest amelioration of symptoms, providing tangible improvements in cognitive function, memory formation and retrieval, and interpersonal behavior.

Finally, the pace of basic science research into AD continues to gain momentum. The accumulation of knowledge of the pathophysiological basis of AD will serve to guide future diagnostic and treatment modalities, and the importance of continued investigation cannot be overstated.

CONCLUSION

Since Alzheimer's observations, more than 100 years ago, of the pathological hallmarks of the disease that would later bear his name, tremendous progress has been made in the many areas reviewed in this chapter. Remarkably, the pace of discovery into the biological basis of AD continues to accelerate. Inevitably, perspectives on the findings presented here will change as new discoveries are made. Exciting progress can be anticipated on several fronts. Genes at several chromosomal loci linked to AD will likely be identified in the near future. The study of the biology of the gene products will yield insights into the basic biological processes at play in the disease. The role of diet and environmental factors in AD will continue to evolve, and the roles of gene–environment interactions will follow. Existing theories of etiopathogenesis undoubtedly will be modified, and new theories will arise.

We can also safely anticipate that the improved understanding of the biology of AD will have a huge impact on clinical practice. New insights into the biology of AD will help in the identification of biomarkers and in the development of novel strategies to aid in early diagnosis and guide therapy. The neuropharmacology for this disease will continue to shift from an approach based on simple

neurotransmitter replacement to one that capitalizes on the multiplicity of receptors and signaling pathways to develop more effective and better-tolerated medications to ameliorate symptoms. Moreover, the neuropharmacology will evolve together with the knowledge of etiopathogenesis to focus on new disease-modifying therapies.

Chapter 49. Neurobiology of Substance Abuse and Addiction

NEUROBIOLOGY OF SUBSTANCE ABUSE AND ADDICTION: INTRODUCTION

Drug addiction is characterized by pathological motivation for drug-seeking and -use behaviors associated with the inability to inhibit such behaviors in spite of their clear adverse consequences (Kalivas and Volkow 2005). These features are clinically operationalized as a diagnosis of drug dependence based on an individual's fulfilling at least three of seven criteria defined by DSM-IV-TR (American Psychiatric Association 2000). The authors conform to the position (O'Brien et al. 2006) that drug *addiction* rather than *dependence* is more appropriate in referring to this maladaptive behavioral disorder and refer to drug dependence only when referring to clinical populations defined by DSM-IV-TR criteria. Drug addiction represents a major public health concern due to its high population prevalence, associated suffering and disability, and limited efficacy of extant therapies to promote recovery and relapse prevention. Understanding the underlying neurobiology of drug abuse and addiction offers the best promise to control drug addiction by identifying the bases of risk for addiction and targeting intervention strategies, uncoupling relapse from its precipitants, and minimizing the personal and social burden of addiction. This chapter represents a critical review of the current state of this understanding and a synthesis of knowledge into present and future directives for managing drug abuse and addiction. The treatment here of this topic is not meant to be comprehensive, but rather focuses on the authors' prioritization of those scientific areas of discovery that are perceived to be most relevant to curbing drug addiction. Attempts have been made to direct interested readers to more exhaustive treatments of less prioritized areas of addiction research findings.

Using a theoretical model of the addiction process (Figure 49–1), this review focuses on the neurobiological events that underlie the transition from initial drug use to addiction, the events that maintain its enduring nature, and the events that underlie the immense socioeconomic costs of being drug addicted. This stage model is introduced, and several examples of population stratifying factors that alter a simple neurobiological explanation are discussed. Next, the major tools of neurobiological investigation of the addiction process are discussed. The neurobiology of the acquisition/transition stage of the addiction process is then discussed, as well as its modulation by genetic, environmental, and neurodevelopmental factors. A major section of this chapter deals with the burgeoning neurobiology of the chronically relapsing nature of drug addiction and focuses on contrasting the three major precipitants of relapse. This section is followed by a discussion of the little-studied neurobiology of the immense socioeconomic costs of end-stage drug addiction and of the relapse prevention and recovery goals of addiction therapies. Finally, a closing, brief discussion of perceived future directions for addiction neuroscience research is provided.

FIGURE 49–1. Theoretical model of the causes and consequences of drug addiction.

Copyright © American Psychiatric Publishing, Inc., or American Psychiatric Association, unless otherwise indicated in figure legend. All rights reserved.

A three-stage model is proposed that entails the addiction process from initial drug use, the transition to chronic drug abuse and addiction, the chronically relapsing nature of addiction, and the social and personal costs of end-stage addiction. The roles of learning, memory, reward sensitivity, and emotion regulation are highlighted. Factors that positively and negatively modulate the addiction acquisition stage are shown. *Psychosocial* factors include the influence of peers, family, cultural variables, social and religious beliefs, socioeconomic status, drug attitudes, and the illicit versus licit nature of the drug of abuse. *Genetic* factors include allelic and haplotypic variation for genes regulating cognitive functions, drug pharmacokinetics and pharmacodynamics, and personality traits. *Neurodevelopmental* factors include risks posed by the adolescent period and by childhood maltreatment. Brain anatomical and neurotransmitter substrates are proposed for the different stages of the addiction process. CRF = corticotropin-releasing factor; OFC = orbitofrontal cortex; SES = socioeconomic status.

THE DRUG ADDICTION PROCESS

The organization of this discussion of the neurobiology of drug abuse and addiction is based on a now-common view of addiction as a multistage process (see Figure 49–1).

This theoretical framework involves an addiction process that extends from initial drug use to the long-term consequences of end-stage addiction and focuses on the three stages of acquisition of the addicted state, its maintenance as a chronically relapsing state, and the long-term personal and social sequelae or consequences of end-stage drug addiction. In this model, drug abuse acquisition and subsequent addiction are mediated by a transition of drug incentives from reinforcing to habit-based effects associated with altered reward sensitivity, which is positively and negatively modulated by multiple factors, and mediated by maladaptive alterations in patterns of neural activity in striatal and frontal cortical areas and their modes of functional connectivity. In this model, the chronically relapsing nature of the addicted state is maintained by pathological motivations for drug-related behaviors unchecked by a diminished behavioral control that are precipitated by conditioned drug cues, stress, and the drug itself, as well as drug motivation related to a wish to relieve aversive drug withdrawal states. The concept of drug addiction as a disorder of too much gas related to the drug-seeking and -use behaviors associated with too little brakes to stop such behavior is an increasingly used analogy. While less studied as a component of the addiction process, the neurobiology of the social and personal expression of drug addiction is considered here, as these factors underlie the immense socioeconomic costs of addiction. The neurobiology of the drug addiction process is complex and includes numerous population stratifying factors. Noteworthy among these are differences due to the sex of the individuals and their racial and ethnic backgrounds. Although it is beyond the scope of this discussion to treat these factors in detail, we offer the following, as any discussion of the neurobiology of drug abuse and addiction is incomplete without considering these important variables.

Sex Differences in the Addiction Process

There are prominent differences between the sexes in the clinical presentation and neurobiology of drug addiction. While such differences are often described as gender differences, we adhere to their distinction as being based on the categorical distinction between men and

women rather than the gender dimension of masculine and feminine characteristics. Whereas drug abuse and addiction are problems often attributed to men, and males have been the focus of the majority of drug abuse research, women are also clearly affected. However, significant sex differences are apparent in the patterns of drug abuse and addiction. It has been suggested that sex differences in behavioral responses to drugs render women more susceptible to drug addiction than men (Lynch et al. 2002; Quiñones-Jenab 2006). Cocaine-dependent men and women display differing clinical characteristics in that women are more likely to have an earlier age at onset of cocaine use than men, women tend to use more cocaine on more days in a given month and take less time to become addicted following initial drug use compared with men, and women enter treatment earlier and present a greater severity of abuse when admitted to treatment programs (Griffin et al. 1989; Kosten et al. 1993; R. D. Weiss et al. 1997). Cocaine-dependent women also demonstrate greater depressive symptomatology and severity of family/social problems, while men are more likely to have antisocial personality disorders (Dudish and Hatsukami 1996; Elman et al. 2001; Griffin et al. 1989; Kosten et al. 1993; R. D. Weiss et al. 1997). Although clinical studies imply that cocaine-dependent women are more negatively affected by cocaine than are men, it has been demonstrated that women relative to men have better treatment outcomes in remaining cocaine abstinent at 6-month follow-up (Kosten et al. 1993; R. D. Weiss et al. 1997). McKay et al. (1996) also determined that women are more likely to seek help after relapsing, whereas men engage in self-justification after relapsing.

Differences between the sexes in the neurobiology of relapse to drug seeking and use behaviors are increasingly apparent. Cocaine-dependent men and women activate different regions of the brain when exposed to drug- and stress-related cues. Clinical research studies have demonstrated that women compared to men have higher levels of drug craving when exposed to drug cues (Elman et al. 2001; Robbins et al. 1999). Women and men exhibit different patterns of neural activation in response to conditioned cocaine cues, which suggests that drug cue–induced relapse involves differing neural pathways in men and women (Kilts et al. 2001, 2004). Cocaine craving in women was associated with less activation of the amygdala, insula, ventral cingulate cortex, and orbitofrontal cortex and greater activation of the anterior cingulate cortex compared with men. Cocaine-dependent women, compared to their male counterparts, showed greater stress-induced activation of the inferior frontal cortex, left insula, dorsal anterior cingulate cortex, and right posterior cingulate cortex (C. S. Li et al. 2005). These results are consistent with the contention that women exhibit less cocaine addiction–related pathology of the frontal cortex than do men (Chang et al. 1999; Levin et al. 1994).

Racial and Ethnic Differences in the Addiction Process

Racial and ethnic differences in socioeconomic status and cultural acceptance contribute to a differing exposure and vulnerability to a host of social problems, with one of the most problematic being drug abuse and addiction. For some drug addictions, the personal and social costs of drug addiction are disproportionately greater for blacks and Hispanics relative to their white counterparts (Wallace 1999). For example, African Americans and Hispanics represent the majority of arrests and incarceration for drug-related crimes in the United States (King and Mauer 2002). Stratifying factors such as allele frequency for risk genes, personality characteristics, substance use among family members and friends, level of drug availability, and neighborhood poverty can all influence drug abuse and addiction in various populations (Wallace 1999). Elevated risk can also be attributed to racial and ethnic group differences in socioeconomic factors such as income, net worth, employment, and poverty. Social frameworks and the neighborhood environment can also be disadvantageous as blacks and Hispanics are more likely to live in rural and urban areas of concentrated poverty (Jones-Webb et al. 1997). A recent functional magnetic resonance imaging (fMRI) study compared African American and white smoking populations and demonstrated that differences in the brain response to smoking cues exist between African American and white smokers (Okuyemi et al. 2006). This difference in the neural representation of relapse suggests racial group differences in the neurobiology of nicotine addiction that, further, may contribute to differences in the effectiveness of drug addiction treatments for individuals of different racial and ethnic backgrounds. Increasingly recognized differences in risk factors for drug abuse and addiction related to racial and ethnic backgrounds warrant a greater future emphasis on these complex population variables when characterizing the neurobiology of drug addiction. Such research is necessary to define, identify, and study high-risk populations for drug addiction.

NEUROSCIENTIFIC APPROACHES TO THE DRUG ADDICTION PROCESS

The neuroscience of drug abuse and addiction represents a rapidly advancing edge in the larger field of discovery related to the biological bases of psychiatric disorders. Much of this recent scientific progress is attributable to the evolving tools and technologies available to addiction researchers and their complementary use. Here we focus on two such tools or technologies: animal models and in vivo neuroimaging approaches.

Animal Models

Animal models of normal and abnormal human behavior have value as simpler, more accessible analogs of complex, inaccessible human conditions. Animal models of the drug addiction process represent arguably the best validated, most widely used animal models of psychiatric disorders. The interested reader should consult Shalev et al. (2002) for a more thorough description of animal models of the drug addiction process. There are numerous animal behavioral models that have been developed and used extensively to elucidate the human drug addiction process. Here we consider the condition place preference (CPP) paradigm and the reinstatement model. The CPP paradigm models the ability of contextual cues associated with drug states to provoke drug-seeking behavior as a function of their properties as rewards (Calcagnetti and Schechter 1993; Schechter and Calcagnetti 1998). The CPP paradigm is based on classical (Pavlovian) conditioning, as contextual cues acquire secondary reinforcing (conditioned stimulus [CS]) properties through their temporal pairing with a psychoactive drug that functions as an unconditioned stimulus (US) (Calcagnetti and Schechter 1993). In this model, a drug is administered to an animal immediately before placement in an environment with distinctive contextual stimuli (olfactory, visual, tactile). Drug-seeking behavior related to the reinforcing property of a drug is then subsequently assessed by the animal's preference for the drug-paired versus unpaired environment expressed in time spent in each environment.

As discussed below, drug addiction is characterized by the high rate of relapse related to drug-seeking and -use behaviors. The reinstatement animal model of relapse represents a critical tool in attempts to characterize the neural mechanisms of relapse and the development of medications promoting relapse prevention in addicted human populations. In the self-administration version of the reinstatement procedure, drug addiction–related relapse refers to the precipitated resumption of drug seeking after extinction of drug-reinforced responding (Epstein et al. 2006; Fuchs et al. 2003; Lynch et al. 2002; Shaham et al. 2003). In reinstatement, operant responding (e.g., lever pressing) resulting in drug self-administration is extinguished after a period of drug availability. Following extinction, noncontingent presentation of the previously self-administered drug (Shaham et al. 2003) or exposure to conditioned drug cues

or stressors reinstates responding (Brown and Erb 2007; de Wit and Stewart 1981; Fuchs et al. 1998; Goddard and Leri 2006; Meil and See 1996; Shelton et al. 2004; Worley et al. 1994). The similarity of these relapse precipitants between the animal model and human drug addiction renders significant face validity to the reinstatement model (Epstein et al. 2006). The model also has good predictive validity and unestablished but building construct validity as an animal model of relapse associated with addiction (Epstein et al. 2006). Reinstatement can also be modeled using the CPP paradigm in which CPP is induced by drug administration, extinguished, and then reinstated by drug-priming injections (Mueller and Stewart 2000). Thus, the drug reinstatement model in animals has important and valid utility in exploring the factors underlying relapse in drug-addicted individuals.

Although animal behavioral models represent valuable tools in exploring the acquisition and maintenance of human drug addiction, genetic animal models provide further insights into the brain mechanisms involved in the acquisition and maintenance of drug addiction. Cocaine blocks the activity of neuronal plasma membrane transporters for dopamine (DAT [dopamine transporter]) as well as serotonin (SERT [serotonin transporter]) and norepinephrine (NET [norepinephrine transporter]) (Kuhar et al. 1991). Genetic models of transgenic knockout mice for these transporters have been studied extensively in establishing the role of each monoamine transporter in the neuropharmacology of cocaine. DAT knockout mice self-administer cocaine and exhibit cocaine-induced CPP (Giros et al. 1996; Medvedev et al. 2005; Rocha et al. 1998; Sora et al. 1998). Knockouts of SERT and NET also display cocaine reward or reinforcement (Sora et al. 1998; Xu et al. 2000). Mice with no DAT and either no or one SERT gene copy display no cocaine-induced CPP (Hall et al. 2002; Shen et al. 2004; Sora et al. 2001). This example suggests that DAT inhibition is not solely required for the reinforcing effects of cocaine. Animal genetic models represent powerful tools in the study of the drug addiction process.

In Vivo Molecular, Anatomical, and Functional Neuroimaging

The development of in vivo neuroimaging technologies such as positron emission tomography (PET), single photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI) has dramatically altered the study of the relationship between the brain and behavior. These technologies have furnished important, novel insights into the neurobiology of the addiction process; specific examples are provided in other sections of this chapter.

The radiometric imaging procedures PET and SPECT represent scanners designed to provide two-dimensional and three-dimensional localizations of photon emissions resulting from radionuclide decay for radiopharmaceuticals that react with or bind to brain proteins involved in the regulation of neurotransmission. Such proteins include enzymes, receptors, and transporters. Although the number of valid PET radioligands that satisfy the requisite affinity, selectivity, metabolic stability, binding site kinetics, and physicochemical properties is limited, the strength of this imaging modality lies in the potential diversity of brain "functions" that can be imaged. Images of neurotransmitter receptor density and occupancy, neurotransmitter release, neurotransmitter synthesis, and metabolic and blood flow corollaries of neural activity in human and nonhuman primates and in small animals have been acquired in support of drug addiction research.

As a nonradiometric imaging technology, MRI also offers multimodal imaging opportunities based on the spatial tuning using gradient coils of the behavior of protons in a large magnetic main field. Optimized pulse sequences permit the acquisition of MRI of hemodynamic corollaries of neural activity, of brain gray and white matter, and of neurochemicals. Images of brain gray and white matter support morphometric and morphological magnetic resonance imaging (mMRI) of the roles of altered brain anatomy in the drug addiction process. For example, drug addiction has been linked to abnormal patterns of regional gray and white matter volumes or densities in the brain of drug-dependent individuals using voxel-based morphometry (VBM). Cocaine- and alcohol-dependent individuals had decreased gray matter densities in the amygdala, frontal cortex, orbitofrontal cortex, cingulate gyrus, temporal cortex, cerebellum, and premotor cortex when compared with control individuals (Franklin et al. 2002; Matochik et al. 2003; Mechtcheriakov et al. 2007; Sim et al. 2007). Numerous examples of the application of in vivo functional neuroimaging approaches such as fMRI and PET to the investigation of the neurobiology of the drug addiction process are discussed in subsections of this chapter; fewer illustrations of the application of magnetic resonance spectroscopy (MRS) are also provided. These examples illustrate the argument that in vivo brain imaging technologies have led to unparalleled advances in the understanding of the neural basis of the acquisition and maintenance of human drug addiction.

THE ACQUISITION OF ADDICTION

Many individuals experiment with drugs of abuse. For many and perhaps all such drugs, their activation of the mesolimbic dopamine projections to the ventral striatum plays a pivotal role in their reinforcing effects (Abi-Dargham et al. 2003; Rodd-Henricks et al. 2002; Volkow et al. 1997), resulting in further experimentation. However, while exact numbers are lacking, only a small percentage of individuals who try drugs of abuse proceed to the compulsive and uncontrolled abuse that characterizes addiction. Individuals comprising this minority share a predisposition that is generally attributed to genetic or environmental factors and their interactions.

The neurobiology of the transition by some susceptible individuals from drug abuse to addiction has been best informed by animal models of drug self-administration. Rats given extended versus limited access to cocaine or heroin self-administration exhibit an escalation of drug intake and an enhanced reinstatement of extinguished drug-seeking behavior by the systemic administration of the self-administered drug—responses that represent well-accepted symptoms of human drug addiction (Ferrario et al. 2005; Knackstedt and Kalivas 2007; Koob and Kreek 2007; Lenoir and Ahmed 2007). Whether this transition occurs in the presence or absence of behavioral sensitization of drug effects remains controversial (Ferrario et al. 2005; Knackstedt and Kalivas 2007; Lenoir and Ahmed 2007). The specific neuroadaptations that underlie this transition include empirical and theoretical accounts of altered striatal and prefrontal cortex circuits. One model attributes the acquisition of addiction to a synaptic reorganization of the core subdivision of the nucleus accumbens that results in a pathological increase in the incentive value of drugs (Ferrario et al. 2005). Another model emphasizes an allostatic decrease in reward system responsivity as the mechanism of escalated drug intake (Ahmed and Koob 2005). A third model emphasizes a neural transition from prefrontal cortical to striatal control over drug-seeking and drug-use behavior and a progression from ventral to more dorsal divisions of the striatum (Everitt and Robbins 2005). The significance of the dorsal striatum and its dopaminergic innervations to the transition from drug use to abuse to addiction is supported by their demonstrated roles in habit formation in humans and animal models (Faure et al. 2005; Yin et al. 2004).

In addition to striatal and frontal cortex involvement in the acquisition of drug addiction, other brain areas code the associative learning and memories reflecting the conditioning of the reinforcing actions of drugs of abuse with the environmental and other contexts of drug use that

promote further conditioned drug abuse. Inactivation of the basolateral amygdala disrupts the learning of the conditioned reinforcing effects of drug-paired stimuli (Kruzich and See 2001). The well-recognized role of the hippocampus in the formation and processing of contextual memories (Holland and Bouton 1999) suggests its involvement in the formation and retrieval of cognitive representations of contextual memories of drug reinforcement. The critical role of the dorsal hippocampus and its projections in the ventral subiculum in the drug cue–induced reinstatement of drug-seeking behavior (Fuchs et al. 2005; Sun and Rebec 2003; Zhao et al. 2006) supports their involvement in the retrieval of associative memories of drug reinforcement. However, the dorsal subiculum may have a selective role in the formation of contextual memories of drug reinforcement as its transient inactivation during conditioning blocked the acquisition of drug-seeking induced by drug-paired stimuli in the reinstatement model (Martin-Fardon et al. 2008). Collective insights from animal models yield a neurobiology of the acquisition of drug-addicted states that includes the engagement of limbic, striatal, and prefrontal cortex areas in drug-related behavioral reinforcement and learning and memory processes that imbue drug-related stimuli with incentive motivation, rewarding, contextual, and habitual properties.

Genetic Influences

Human studies of the neurobiology of the transition from drug use to abuse and addiction have focused more on the roles played by genetic and environmental risk factors (see Figure 49–1). Environmental and genetic factors contribute to individual differences in vulnerability to initiating use of drugs of abuse and in vulnerability to the shift from drug use to addiction (Goldman et al. 2005). Drug addictions represent some of the most heritable psychiatric disorders. Heritabilities differ for different drug addictions, ranging from moderate values (0.39) for hallucinogens to high heritabilities (0.72) for cocaine (Goldman et al. 2005). Estimated heritabilities for the initiation and use of drugs of abuse are typically lower than those for addiction (M. D. Li et al. 2003). The obvious questions are what exactly is being inherited by individuals and populations that enhances the risk for drug use and addiction, and what are the relative contributions of genetic and environmental factors to the observed heritabilities? The genetic determinants of drug abuse and addiction include the regulation of pharmacodynamic and pharmacokinetic processes that determine drug sensitivity and the genetic regulation of intermediate cognitive, personality, and other phenotypes that influence the addiction process (Goldman et al. 2005). The neurobiological corollaries of the genetics of addiction that confer vulnerability for, and protection from, drug abuse and addiction are in an early stage of identification. The emerging field of "imaging genetics" (Meyer-Lindenberg and Weinberger 2006) is based on the use of in vivo neuroimaging approaches to define the neurobiology mediating the influence of genetic variation on the expression of normal and abnormal human behavior. These approaches provide clues as to what is being inherited in the form of identified gene influences on brain morphology and morphometrics, task-related brain activity, functional and anatomical connectivity between brain areas comprising neural circuits and pathways, and the expression and occupancy of neurotransmitter receptors, transporters, and enzymes.

Due to the demonstrated roles of neurotransmitter alterations in the addiction process, variations in genes that regulate neurotransmission have been the primary focus of efforts to identify addiction-related genes. Quantitative trait locus (QTL) analyses of ethanol-related behaviors including preference and sensitivity to withdrawal and sedation in mice implicate gene clusters harboring the γ aminobutyric acid A ($GABA_A$) receptor (Crabbe et al. 1999). While a detailed discussion of the neurobiology of genetic risk for drug abuse and addiction is beyond the scope of this chapter, we offer the following as examples of the impact of, and insights from, early approaches.

Dopamine-related genes have been implicated in the addiction process, particularly functional polymorphisms for genes encoding catechol-*O*-methyltransferase (*COMT*), the human dopamine transporter (*DAT1*), and the D_2 and D_4 dopamine receptors (*DRD2* and *DRD4,* respectively). The level of expression of D_2 receptors in the prefrontal cortex as defined by [^{11}C]raclopride PET imaging determines the subjective experience of pleasure following the administration of methylphenidate and presumably other psychostimulants (Volkow et al. 2005). Interindividual differences in the structure or expression of genes involved in dopaminergic neurotransmission (e.g., *DRD2*) could account for some of the genetically mediated variability in substance abuse behaviors in humans (Uhl et al. 1993). Allelic variation for the *DRD2* Taq1 restriction fragment length polymorphism (RFLP) regulates the craving response to conditioned drug cues associated with nicotine (Erblich et al. 2005) and heroin (Y. Li et al. 2006) addiction. Recent [^{11}C]raclopride PET imaging studies indicate that variable number of tandem repeat (VNTR) polymorphisms in the *DAT1* and *DRD4* genes, and a single nucleotide polymorphism (SNP) in the *COMT* gene, regulate the release of ventral striatal dopamine in response to cigarette smoking, with the response inversely related to cigarette craving (Brody et al. 2006). Many studies also suggest that *SLC6A3,* the gene that encodes DAT, has a genetic link with cocaine addiction (Haile et al. 2007). Individual variation in dopamine-related genes may thus regulate individual differences in acquisition of drug addiction and risk for relapse.

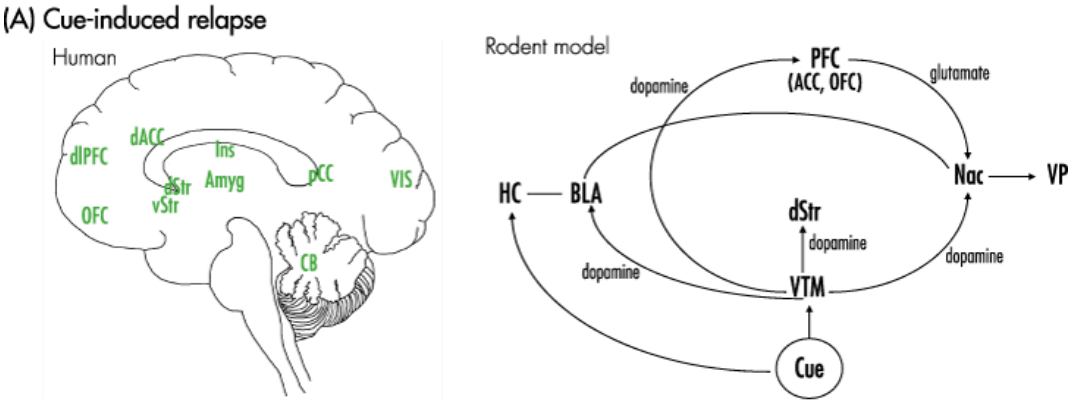
The genetic regulation of cognitive functions related to the addiction process, or of personality traits that modulate risk for drug abuse and addiction, represents another source of the observed heritability of addictive disorders (Kreek et al. 2005). Personality traits such as impulsivity, risk taking, and novelty seeking are associated with drug addiction (Moeller et al. 2001) and with risk for drug abuse and addiction (Dawe and Loxton 2004; Kreek et al. 2005). These traits are regulated by serotonin-related genes that encode the brain isoform of tryptophan hydroxylase (*TPH2*) (Zhou et al. 2005) and the serotonin transporter (SERT) (Gerra et al. 2005). Allelic variation of the TPH2 gene (*TPH2*) and the SERT gene (*5-HTTLPR*) regulates the neural response to demands for cognitive and affective processing (Canli et al. 2008; Herrmann et al. 2007). Similarly, cognitive functions related to the addiction process, such as inhibitory executive control, the processing of incentives and rewards, and delay discounting, have a neurobiology that is profoundly influenced by polymorphic variation in genes regulating dopamine neurotransmission. Putative functional polymorphisms in *COMT* and *DAT1* additively regulate the neural basis of reward sensitivity (Yacubian et al. 2007) and thus, potentially, vulnerability to drug abuse and addiction. Importantly, genes that regulate pharmacodynamic, pharmacokinetic, and cognitive functions and personality traits exhibit epistatic gene–gene interactions that convey multiplicative contributions to risk for drug abuse and addiction in allele carriers (Yacubian et al. 2007).

Environmental Influences

Genetic factors explain, on average, only about half of the total variability in drug addiction, with the remaining variability influenced by environmental factors. Also, genetic risk may be differentially expressed in the presence versus absence of particular environmental conditions (Lessov et al. 2004). Environmental factors that can contribute to drug abuse and addiction include psychosocial factors such as socioeconomic status, peer influence, and family dissension and early-life adversity such as physical, sexual, and emotional abuse and/or neglect (see Figure 49–1). More than half of drug abusers entering addiction treatment report a history of childhood physical or sexual abuse (Pirard et al. 2005). High rates of childhood maltreatment (e.g., childhood physical, sexual, and emotional abuse and/or neglect) have

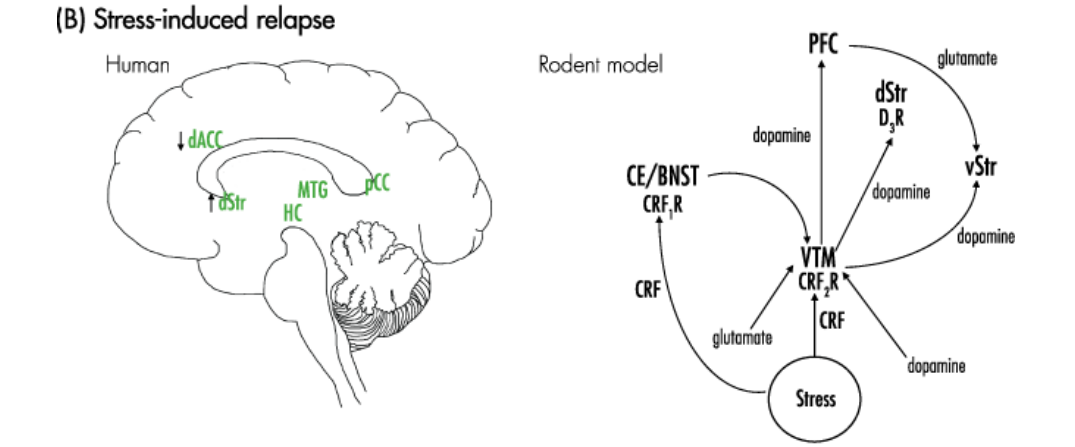
been associated with drug abuse and addiction (Simpson and Miller 2002). Studies also suggest that relationships between drug use and abuse and childhood maltreatment are stronger in women (Hyman et al. 2005; MacMillan et al. 2001). Childhood maltreatment was also associated with a younger age of first cocaine use and a greater lifetime severity of drug use (Hyman et al. 2006). Women also typically had more instances of sexual and emotional abuse and overall childhood maltreatment, while in men emotional abuse was the main type of abuse reported. Recent findings suggest that having a history of childhood maltreatment may influence how recently abstinent cocaine-dependent individuals experience and cope with stress, a recognized relapse factor (Hyman et al. 2007). Cocaine-dependent individuals have a higher incidence of trauma and comorbid posttraumatic stress disorder (PTSD) (Back et al. 2000). The neurobiology of childhood abuse and neglect is intimately intertwined with the neurobiology of drug abuse and addiction. For instance, the observation that childhood maltreatment is associated with a persistent, perhaps permanent, sensitization of the endocrine and autonomic response to stress (Heim et al. 2000) implies a related sensitization of drug-addicted individuals with childhood maltreatment histories to stress-induced relapse. The impossibility of understanding the neurobiology of the acquisition of drug addiction without appreciating the genetic and environmental determinants of individual differences in the risk for abuse and addiction and in the response to addiction therapies is increasingly obvious.

Neurodevelopmental Influences



Adolescence is a time of high-risk behavior and increased exploration. The neurodevelopmental period of adolescence represents typically the first experimentation with drugs of abuse and is associated with an increased risk to develop drug addiction in adulthood (see Figure 49–1). Adolescents typically exhibit higher rates of experimental drug use and abuse disorders than adults (Chambers et al. 2003). Recognized risk factors for adolescent drug abuse include early marijuana and cigarette use, deviant behavior, negative family interactions, poor parent–child communication, school disengagement, family drug problems, drug availability, and prodrug attitudes and intentions (Ellickson and Morton 1999; Kliewer and Murrelle 2007). Adolescence also represents a critical period for factors such as parental support or nonfamily mentors to exert their durable protective effects on drug abuse and addiction. Adolescence is a critical period for maturation of neurobiological processes that underlie higher cognitive functions and social and emotional behavior (Yurgelun-Todd 2007). Functional neuroimaging studies indicate that brain regions that underlie attention, reward evaluation, affective discrimination, response inhibition, and goal-directed behavior undergo structural and functional organization throughout late childhood and early adulthood (Bjork et al. 2004; Galvan et al. 2006; Yurgelun-Todd 2007). The vulnerability of adolescents to drug abuse and addiction may reflect the delayed brain maturation of executive processes of behavioral regulation relative to those that encode incentive valuation. Adolescents, relative to children and adults, exhibited increased nucleus accumbens activity relative to prefrontal cortex activity during reward valuation, whereas the orbitofrontal cortex response was similar to that of children and less than that of adults (Galvan et al. 2006). Greater motivational drives for rewards, coupled with an immature neural mechanism of inhibitory control, could predispose adolescents to impulsive actions and risky behaviors including experimentation with drugs of abuse (Chambers et al. 2003). Elucidating the developmental timing of the neural processing of incentive valuation, goal representation, delay discounting, response inhibition, and other behaviors related to the addiction process using technologies such as fMRI over the adolescent period would clearly inform the pathogenesis of substance use disorders and inform intervention strategies for preventing drug abuse and other high-risk behaviors in youth.

RELAPSE TO DRUG-SEEKING AND DRUG USE BEHAVIORS



Drug addiction in treatment-seeking individuals is associated with high rates of recidivism (O'Brien 1997). Attentional and motivational responses to conditioned drug cues represent powerful precipitants of relapse in drug-addicted individuals (Kalivas and Volkow 2005). There has been scant research focusing on identifying neural markers of relapse in drug-dependent human populations, in spite of the clear value of such predictors to defining relapse risk and treatment prognosis. A recent fMRI study in treatment-completing methamphetamine-dependent subjects examined the relationship between the magnitude of the distributed neural response to a decision-making task and the incidence of relapse over a 1-year follow-up interval (Paulus et al. 2005). Lower task-related activation of the right middle frontal gyrus, middle temporal gyrus, and posterior cingulate cortex best predicted time to relapse. These predictive neural responses suggest their representation of deficit functions related to decision making that bias individuals for relapse.

The process of relapse to drug-seeking and -use behavior is multidetermined, with at least three putative precipitants that are recognized in drug-addicted human subjects and reliably modeled in reinstatement versions of animal drug self-administration paradigms (Figure 49–2). The formation of learned associations between drug-use reminders, or cues, and the euphoria or "high" associated with drug use underlies the pathological motivations for drug seeking and use that define relapse due to *conditioned drug cues* (Figure 49–2A). Such cues are diverse in nature and include exteroceptive stimuli, such as persons, places, or sensory cues, as well as interoceptive stimuli, such as mood states. The experience of *stress* represents a second well-recognized precipitant of relapse (Figure 49–2B). *Drug use itself* is also recognized as a precipitant of motivation for further drug abuse in the form of drug bingeing (Figure 49–2C). The interested reader should consult Epstein et al. (2006) for a thoughtful discussion of the validity of the reinstatement procedure as an animal model of drug relapse.

To elucidate the emerging neurobiology of mechanisms of relapse to drug-seeking and -use behaviors associated with drug addiction, we consider and compare three potential precipitants of relapse: conditioned drug-use reminders or cues **(A, Cue-induced relapse model),** stress **(B, Stress-induced relapse model),** and use/administration of the drug itself **(C, Drug-induced relapse model).** For each model presented, the neuroanatomical areas and neurotransmitter mechanisms involved (as defined by investigation of the reinstatement animal model of relapse) are shown *on the right,* and the distributed neural processing associated with experiencing the relapse precipitant (as defined by human in vivo functional neuroimaging studies in males) is shown *on the left.* It should be emphasized that these neurobiological mechanisms reflect major but not all research findings and represent an as-yet-incomplete characterization of the mechanisms of relapse. Therefore, strict comparisons of the underlying mechanisms between the three relapse precipitants should be done with caution.

ACC = anterior cingulate cortex; Amyg = amygdala; BLA = basolateral amygdaloid nucleus; BNST = bed nucleus of the stria terminalis; CB = cerebellum; CE = central amygdaloid nucleus; CRF = corticotropin-releasing factor; CRF_1R = corticotropin-releasing factor 1 receptor; CRF_2R = corticotropin-releasing factor 2 receptor; D_3R = D_3 dopamine receptor; dACC = dorsal anterior cingulate cortex; dlPFC = dorsolateral prefrontal cortex; dStr = dorsal striatum; HC = hippocampus; Ins = insula; lOFC = left orbitofrontal cortex; mCC = middle cingulate cortex; MTG = medial temporal gyrus; Nac = nucleus accumbens; OFC = orbitofrontal cortex; pCC = posterior cingulate cortex; PFC = prefrontal cortex; VIS = visual cortex; VP = ventral pallidum; vStr = ventral striatum;

VTM = ventral tegmentum.

The human motivational state for drug use that propels drug-seeking behavior is often referred to as "craving." Empirically, drug craving is defined by subjective measures of self-rated intensities of craving, using Likert or other scales, or by objective measures of craving-related arousal, such as skin conductance, heart rate, blood pressure, or pupil diameter. The following describes research findings related to the functional neuroanatomy and neurochemistry of precipitated drug craving defined by animal models or human neuroimaging studies. While often assumed, the true relationship between craving and relapse is complex and only modestly established at this time (Epstein et al. 2006). It is also noteworthy that a neuroanatomy of precipitated drug seeking based on the collected findings from even a single animal model is less than definitive as different means of probing the involvement of a given brain area (e.g., tetrodotoxin, receptor antagonists or agonists, lesions) yield conflicting outcomes (Bossert et al. 2005). As such, the following discussion of the neurobiology of relapse comparing the drug-seeking condition defined by the reinstatement animal model and human drug craving defined in the laboratory should be critically considered.

Relapse Related to Conditioned Drug Cues

In drug-dependent subjects, exposure to drug-related stimuli (e.g., drug paraphernalia, drug-taking environment) elicits intense craving and increases the probability of relapse even following prolonged abstinence (Childress et al. 1988; Ehrman et al. 1992; Jaffe et al. 1989; Johnson et al. 1998). The neural representation of conditioned cue–induced drug craving has been explored in the reinstatement model in rats, in which a conditioned stimulus (e.g., a light) that was paired with access to cocaine in a self-administration paradigm reinstates drug-seeking behavior (i.e., lever pressing) following extinction of the drug access contingency of the lever. Understandably, there is considerable overlap of affected brain regions with brain regions thought to be involved in appetitive conditioning and the retrieval of conditioned associations (Kelley et al. 2005; See 2002; Thomas and Everitt 2001). A combination of results from lesioning and pharmacological inactivation studies, intracerebral microdialysis, electrophysiology, and molecular markers of neuronal activity implicates the amygdala (Hayes et al. 2003; Thomas and Everitt 2001), the anterior cingulate and orbitofrontal cortex (McLaughlin and See 2003), and the dorsal (Ito et al. 2002) and ventral (Ghitza et al. 2003) striatum in the drug motivational response to conditioned drug cues (Figure 49–2A).

Beyond their use in elucidating the neuroanatomy of conditioned cue–induced drug craving, animal models have uniquely contributed to our understanding of the specific neurotransmitters involved in the coupling of drug-predictive stimuli with drug-seeking behavior. Conditioned drug cues are associated with glutamate release in the nucleus accumbens and dopamine release in the amygdala, nucleus accumbens, dorsal striatum, and prefrontal cortex (Ito et al. 2002; Phillips et al. 2003; Vanderschuren et al. 2005; F. Weiss et al. 2000) (see Figure 49–2A). It is noteworthy that the neuroanatomy and neurobiology of drug seeking precipitated by conditioned drug cues differs when the drug-paired cue is a discrete cue, discriminative cue, or contextual cue (Bossert et al. 2005). Interested readers should consult Kalivas and Volkow (2005) or Bossert et al. (2005) for more elaborated models of the roles of alterations in cellular signaling, receptor translocation, and cell morphology in the neural basis of the relapse process.

In vivo functional neuroimaging approaches have provided novel insights into the distributed patterns of neural processing that transduce the experience of conditioned drug-use reminders into drug craving and relapse in human drug addicts. Here, a clear challenge has been to capture the neural response to drug cues within the nonnaturalistic environment of a PET, SPECT, or MRI scanner for drug-use reminders that are highly individualized and context-dependent. In response to these challenges in experimental design, researchers have devised generalized drug cues represented by videotape and still images of drug-use behavior, the handling of drug paraphernalia, individualized drug cues in the form of the mental imagery of personal drug use guided by autobiographical scripts, and compound drug cues represented by virtual reality environments. Additional experimental design challenges are posed by the need to document and quantify the induced drug motivational state and to compare it to responses to control conditions that correct for sensory, motor, attentional, mnemonic, and other features of cue processing. The combination of subjective self-ratings of the intensity of drug-use urges and of corollary emotional states with objective psychophysiological measures (heart rate, skin conductance, pupil diameter, or respiratory rate) of craving-related arousal has emerged as a best approach to defining and quantifying cue-induced drug craving. Implementing the ideal control condition(s) has been a more elusive aspect of experimental design. Finally, the characteristics of the sample of drug-dependent individuals studied represents a critical determinant of the neural response to drug cues. Features such as age, sex (Kilts et al. 2004), duration of drug abstinence, treatment enrollment (Wilson et al. 2003), specific drug dependency, expectancy of drug availability (McBride et al. 2006; Wertz and Sayette 2001), comorbid psychiatric illness or drug dependencies, or experiences of recent stress or early-life adversities critically modulate the neural processing of conditioned drug cues. The interested reader should consult Kilts et al. (2001) for a more detailed treatment of experimental approaches to the use of in vivo functional neuroimaging technology to define the neurobiology of the drug motivational state.

The neurobiology of cue-induced craving in drug-addicted human subjects exhibits many parallels with findings from the reinstatement animal model (see Figure 49–2A). First, [^{11}C]raclopride PET imaging studies of cocaine abusers demonstrated that the occupancy of D_2 receptors in the human dorsal (but not ventral) striatum was increased by exposure to cocaine cues (Volkow et al. 2006; Wong et al. 2006), and imaging of alcoholic subjects has revealed increased D_2 receptor occupancy in both striatal subdivisions in response to exposure to alcohol cues (Heinz et al. 2004). This cue response presumably reflects a cue-induced increase in dorsal striatal dopamine release and was positively correlated with both the intensity of self-reported cocaine craving and the severity of addiction-related functional impairment. Conditioned cocaine cues increase dorsal striatal dopamine release in cocaine-dependent human subjects and animal models of cocaine self-administration, implicating this cue response in the processing of cues as reward predictors and as a biomarker of the habitual nature of addiction. Second, the distributed neural response to drug cues in drug-dependent human subjects involves many of the same brain areas implicated by the response to discrete drug-paired stimuli in rats.

Figure 49–2 presents a summary of human study findings across diverse experimental approaches. Brain areas activated by the passive or active processing of conditioned drug cues include the anterior and posterior cingulate cortex, amygdala, ventral striatum, insula, orbitofrontal cortex, dorsolateral prefrontal cortex, cerebellum, and visual cortex (Anderson et al. 2006; Bonson et al. 2002; Childress et al. 1999; Daglish et al. 2001; Garavan et al. 2000; Grant et al. 1996; Heinz et al. 2004; Kilts et al. 2001, 2004; Maas et al. 1998; Wexler et al. 2001). The results of correlational and other approaches to data analysis, expanded experimental designs (e.g., the inclusion of attempts to volitionally inhibit the craving response), and comparisons of localized brain responses with other imaging studies furnish plausible

inferences of the roles of each neural activation site to the complex state of conditioned drug craving and relapse. Consistent drug cue–induced activation of the amygdala may reflect the motivational evaluation of emotional and other associations to drug cues (Kilts et al. 2004). Cue-induced activation of the dorsal anterior cingulate cortex (dACC) may reflect the computation of conditional drug probabilities (Kilts et al. 2004) and the related processing of response conflict due to drug nonavailability in the scanner context. Greater dACC activation to drug cues may reflect an adaptive regulatory role that dampens the drug cue evaluative functions of brain areas mediating their sensory and motivational processing when drug availability is low or when drug use is resisted (Brody et al. 2007; Kilts et al. 2004). The dorsolateral prefrontal cortex activation by drug cues may reflect the access to mental representations of drug use and/or the engagement of executive control of drug-related behaviors signaled by the dACC response. Cue-induced activation of the insula may reflect the access of somatic representations of drug states and/or the aversive properties of experiencing drug motivation in the absence of availability. Activation of the ventral striatum by drug cues may reflect the processing of the strong incentive motivational property of drug cues, while activation of the precommissural dorsal striatum may reflect the retrieval of motor cognitions related to habits of drug abuse. These findings suggest a complex relationship between the experiencing of drug-use reminders and motivation for drug abuse. The interested reader should consult Kilts et al. (2001) for a more thorough description of the human functional brain imaging studies and their designs that have investigated the neural response to conditioned drug cues in diverse drug addictions.

Much has been learned about the neurobiology of conditioned drug craving from animal model and human studies. In several instances this knowledge has driven the development of novel treatments for drug addiction. As an example, the findings that the reinstatement of drug-seeking behavior by conditioned drug cues in rats was related to deficits in frontal–striatal glutamate signaling that was rescued by stimulation of the cysteine–glutamate exchanger by administration of the cysteine prodrug *N*-acetylcysteine (Zhou and Kalivas 2008) led to the demonstration that *N*-acetylcysteine administration reduces the urge to use cocaine provoked by drug cues in cocaine-dependent human subjects (LaRowe et al. 2007).

Relapse Related to Stressful Events

Stress is another factor that can precipitate intense drug wanting or craving. The neural representation of stress-induced drug craving has been explored in the reinstatement model in rats in which stressors (typically footshock) reinstate drug-seeking behavior (i.e., lever pressing) following extinction of the drug access contingency of the lever. In this animal model, stress-induced drug-seeking behavior shares many of the neural substrates associated with cue-induced drug seeking including the midbrain ventral tegmentum, prefrontal cortex, and dorsal and ventral striatum (Figure 49–2B).

A glutamatergic projection from the prefrontal cortex to the ventral striatum has been proposed as a final common pathway for the precipitation of drug seeking by stress, conditioned drug cues, or the drug itself (Kalivas and Volkow 2005). The neural pathways associated with stress- and drug cue–induced drug seeking are, however, distinct in other ways (Shalev et al. 2002). Unlike cue-induced drug seeking, stress-primed drug seeking does not involve the basolateral amygdala (McFarland et al. 2004), but rather engages the bed nucleus of the stria terminalis and other brain areas comprising the extended amygdala (Shaham et al. 2002). Stress and drug cues exhibit additive effects on drug seeking related to their shared activation of the corticotropin-releasing factor (CRF) system (Liu and Weiss 2002). However, the role of CRF signaling in stress-induced relapse is particularly important and related to multiple actions at CRF_1 and CRF_2 receptors regulating dopamine and glutamate release in midbrain and forebrain elements of drug motivational pathways (Wang et al. 2007) (see Figure 49–2B).

Recent evidence supports the relatedness of stress-related increases in drug craving to cocaine relapse outcomes in cocaine-dependent individuals (Sinha et al. 2006). The intensity of stress-induced increases in drug craving and hypothalamic-pituitary-adrenal (HPA) axis responses predicted a shorter time to relapse and higher amounts of cocaine use per occasion, respectively. Recent in vivo functional neuroimaging studies have also provided novel insights into the distributed patterns of neural processing that transduce the experience of acute stress into drug craving and relapse in drug-addicted human subjects. In studies employing script-guided mental imagery as a means of exposure to a stressor in a scanner environment, a mixed-sex sample of cocaine-dependent subjects exhibited decreased activation in paralimbic (anterior cingulate) and limbic (hippocampus) regions and increased activation in the dorsal striatal region in response to stress relative to comparison subjects (Sinha et al. 2005) (see Figure 49–2B). The dorsal striatal response scaled with the intensity of stress-induced cocaine craving. The implication of these findings is that stress diminishes responses associated with the self-regulation of affect- and drug-related behaviors and activates the habit pattern of compulsive drug abuse (Sinha et al. 2005). As discussed previously, a comparison of male and female cocaine-addicted subjects supported significant differences between the sexes in the neural response to a stressor, in spite of equivalent anxiety and craving responses (Sinha et al. 2005). Compared with males, cocaine-dependent females exhibited greater paralimbic and left frontal responses, suggesting activation of greater conflict detection and response inhibition in reacting to stress. The functional neuroanatomy of stress-induced drug craving in drug-addicted humans is critically uninformed, as drug dependencies other than cocaine have not been examined and the dependence of observed neural responses on the nature of the acute stress and its interaction with prior and early-life stress has not been defined.

In contrast to the extensive research conducted in animal models, the comparative neurobiology of drug cue–induced and stress-induced drug craving in human addicts has been little explored. A comparison of script-guided mental imagery paradigms indicated that drug cue and stress imagery in cocaine-dependent subjects similarly activated the HPA and autonomic components of the stress response system (Sinha et al. 2003). Findings from the reinstatement animal model indicate that stress-induced and drug cue–induced drug-seeking behavior exhibits an additive interaction (F. Weiss 2005). A recent fMRI study in cocaine-dependent men demonstrated a greater drug cue–induced activation of the posterior cingulate and parietal cortex response in the presence versus absence of an acute stressor (anticipation of electric shock) (Duncan et al. 2007). These results indicate that stress and conditioned drug cues interact to augment drug-seeking behavior and that stress may provoke relapse by activating brain areas involved in processing the incentive and attention biasing properties of drug-use reminders.

Much has been learned about the neurobiology of stress-induced drug craving from animal model and human studies. In several instances this knowledge has driven the development of novel treatments for drug addiction. As an example, the demonstration in rats that activation of α_2-adrenergic receptors by the administration of lofexidine or clonidine attenuated footshock-induced reinstatement of cocaine or heroin seeking (Erb et al. 2000; Shaham et al. 2002) led to the subsequent preliminary demonstration that lofexidine attenuates stress-induced drug craving and promotes drug abstinence rates in opiate-addicted subjects (Sinha et al. 2006).

Relapse Related to Drug Use

The neural representation of drug-induced drug craving has been explored in the reinstatement model in rats in which noncontingent administration of the self-administered drug reinstates drug-seeking behavior (i.e., lever pressing) following extinction of the drug access contingency of the lever. This drug-primed reinstatement of drug seeking has been observed for cocaine, heroin, alcohol, and nicotine self-administration; generalizes to other members of the same pharmacological class; exhibits cross-reinstatement for drugs from different classes than the self-administered drug; and is positively correlated in its magnitude with the priming dose (Shalev et al. 2002). Like stress- and drug cue–induced reinstatement of drug seeking, drug-primed reinstatement involves the prefrontal cortex and its glutamatergic projections to the nucleus accumbens (Bossert et al. 2005; Kalivas and Volkow 2005; McFarland and Kalivas 2001) (Figure 49–2C).

However, evidence from animal models indicates that drug-induced relapse differs neurobiologically from relapse precipitated by conditioned drug cues or stress. While the prefrontal cortex is consistently implicated in the reinstatement of drug seeking, different subregions of the medial prefrontal cortex appear to be involved in drug-induced, drug cue–induced, and stress-induced reinstatement (Capriles et al. 2003; Fuchs et al. 2004).Temporally, mice exhibited a transient (<2 months) drug-primed reinstatement of methamphetamine-seeking behavior following extinction, while cue-induced reinstatement was persistent (>5 months), suggesting the involvement of differing neuroadaptations for the two relapse factors (Yan et al. 2007).

Human in vivo functional neuroimaging studies have examined the neural responses associated with subjective drug abuse experiences, including drug craving. The neurobiology of drug craving, as elucidated through in vivo functional neuroimaging of cocaine's effects in drug-addicted human subjects, also exhibits clear parallels with findings from research paradigms employing the reinstatement animal model of relapse (see Figure 49–2C). Passive delivery of cocaine to cocaine-dependent subjects produced experiences of "high" that were temporally correlated with fMRI responses in the ventral tegmentum, dorsal striatum, and anterior and posterior cingulate cortices, whereas experiences of craving correlated with activity in the ventral striatum, anterior and posterior cingulate cortices, parahippocampal gyrus, and amygdala (negative correlation) (Breiter et al. 1997). A more recent fMRI study examining the neural correlates of "high" and craving during cocaine self-administration noted that self-reported craving correlated positively with activity in the anterior cingulate cortex, ventral striatum, and lateral orbitofrontal cortex, whereas cocaine-induced "high" correlated negatively with activity in the same brain regions (Risinger et al. 2005). Cocaine-induced craving was negatively correlated with activity in the middle cingulate cortex and thalamus. A related PET study noted that methylphenidate-induced craving in cocaine-addicted individuals was also associated with activation of the orbitofrontal cortex (Kalivas and Volkow 2005). These convergent findings indicate that the drug motivational state precipitated by noncontingent and contingent drug administration is transduced by the distributed activation of limbic, paralimbic, and striatal brain areas involved in incentive processing/valuation, cognitive control, and habit learning.

NEURAL SUBSTRATES UNDERLYING THE ASSOCIATION OF DRUG ADDICTION WITH IMPULSIVE AGGRESSION AND VIOLENCE

Many of the neuroadaptive responses to prolonged drug intake are enduring and persist even following long periods of drug abstinence. Drug-addicted individuals are vulnerable to relapse for years after initiating and maintaining abstinence. This section deals with the social neuroscience of drug addiction, specifically the impact of end-stage drug addiction on the perception of social signals, the organization of reciprocal social responses, and the regulation of antisocial behavior. Is there a neurobiology of the social cost of drug addiction? A recent characterization of the prevalence and population estimates of violent behavior among individuals with DSM-IV-TR psychiatric disorders demonstrated that substance use disorders were by far the most significant contributors to the public health burden of violent behavior (Pulay et al. 2008). This discussion will focus on the neurobiology of the specific social cost due to the association of drug abuse with escalation of aggression and violence in some drug cultures (Boles and Miotto 2003; Fals-Stewart et al. 2003; Hoaken and Stewart 2003). The introduction of crack cocaine in an urban area in the 1980s was marked not so much by drug arrests as by crimes of assault and emergency room data related to the corollary escalation of aggression and violence. The economic costs of crime related to drug abuse and addiction are enormous. A large proportion of violent and property crimes in the United States involve drugs of abuse. Costs associated with medical care, property loss, future earnings, and adjudication, and pain and suffering associated with drug-related crime exceed $200 billion per year in the United States (Miller et al. 2006). Emergency room studies indicate that 35%–40% of injuries are associated with illicit drug use that is confirmed by toxicology (Vitale and van de Mheen 2006), particularly in association with intentional violent crime (Macdonald et al. 2003). Complex, multifactorial relationships exist between aggressive behavior and drug abuse and addiction that are moderated by situational and personal variables (Ousey and Lee 2004). This stage of the addiction process constitutes the greatest social and personal cost of addiction, yet, paradoxically, has been the least studied and characterized (see Figure 49–1). Key to understanding the escalation of interpersonal aggression and violence associated with some drug addictions is an understanding of its neurobiology in valid animal models and human populations.

Initial insights into the neural substrates of the association of drug addiction with impulsive aggression and violence were provided by the relationship between anger traits (Goldstein et al. 2005) and anger states (Drexler et al. 2000) with decreased neural activity in the lateral orbitofrontal cortex of cocaine-addicted men. These finding suggest that the behavioral regulatory roles of the orbitofrontal cortex and other brain areas are compromised in cocaine addiction, resulting in unchecked impulsive aggression in response to anger-provoking situations. These associations, however, lack the social context necessary to establish a relationship between experiences of anger, inhibitory control failures, and aggressive behavior in drug-addicted populations. Currently, these relationships may be best explored by the combination of in vivo functional neuroimaging technology and game behavior to define the neural responses of drug-addicted individuals to aggressive and affiliative behaviors emitted by playing partners in ongoing social dyadic interactions (Rilling et al. 2002). Such simulated social interactions in the context of game behavior offer novel insights into the impact of state (e.g., drug withdrawal) and trait (e.g., personality, race/ethnicity) variables on the brain response to real-world prosocial and antisocial behaviors. For example, using an iterated prisoner's dilemma game, Rilling et al. (2007) demonstrated that individuals scoring higher on psychopathic traits (versus those scoring lower on such traits) employed a more interpersonally aggressive game strategy that was associated with blunted amygdala responses to unreciprocated cooperation, consistent with less aversive conditioning to these social outcomes. High psychopathy trait scores were also associated with blunted anterior cingulate and dorsolateral prefrontal cortex responses when subjects chose to defect on their playing partners, a finding consistent with lesser conflict and cognitive control related to such antisocial behaviors. A game-based study of reactive aggression in a general population sample indicated that the decision to act aggressively was associated with paralimbic cortex activation consistent with conflict between emotional motivations to act and cognitive control processes regulating the tendency to act impulsively (Kramer et al. 2007). It would seem of significant interest whether drug addiction is associated with diminished functional activation and/or connectivity

in brain areas involved in monitoring or resolving emotional conflict or in implementing cognitive control in response to a stimulus or opportunity for impulsive aggression. The further study of at-risk populations using game-based elicitation of aggression and functional neuroimaging would be useful in exploring a cause-versus-effect explanation of observed neural processing deficits associated with impulsive aggression.

DRUG ADDICTION TREATMENT OUTCOME

Currently used therapies promoting recovery and relapse prevention in drug-addicted individuals are largely behavioral approaches such as 12-Step programs, cognitive-behavioral therapy (CBT), contingency management, and cognitive skills training (Carroll and Onken 2005). Indeed, behavioral therapies for drug addiction represent arguably the oldest, most prevalent forms of behavioral therapy in medicine. These approaches attempt to thwart the addiction process at multiple levels (Table 49–1).

TABLE 49–1. Stages of the addiction process targeted by addiction therapies

Decrease the incentive motivational value of the drug (U.S. devaluation)
Increase the willful control of drug-related behavior
Increase the salience and motivational value of nondrug reinforcers
Inhibit conditioned responses to drug-predictive stimuli

Source. Adapted from Kalivas and Volkow 2005.

Despite the fact that such treatments for drug addiction have long been recognized to be efficacious, surprisingly little research effort has been directed toward examination of the neurobiology underlying treatment-related recovery, relapse prevention, and predictors of treatment response versus nonresponse. This virtual absence of neuroscientific investigation of the efficacy and effectiveness of addiction therapies is related to the fact that the scientific rigor of controlled clinical trial designs has only recently been applied to addiction behavioral therapies (Carroll and Onken 2005) and thus, empirical evidence of their absolute and relative efficacy remains largely unestablished. However, a brief consideration of the largely cognitive underpinnings of major addiction therapies (see Table 49–1) illustrates that fact that they seek to engage the processes of incentive valuation, learning, memory, and inhibitory control that are currently highly active areas of human neuroscience research in non-drug-addicted individuals. Therefore, immense opportunities exist to pair addiction therapies with longitudinal functional neuroimaging studies to define the specific ways in which the brain changes when relapse prevention occurs and to define neural predictors of relapse.

As a relapse prevention therapy, CBT targets the extinction of conditioned drug associations as a means of dissociating cocaine-related cues and intense drug motivations. CBT helps cocaine-dependent individuals "relearn" a distinct association or contingency between conditioned drug cues and drug-seeking and -use behaviors. CBT is based on the tenet that learning processes play an important role in the acquisition and maintenance of drug addiction and that these same learning processes can be used to help individuals reduce their drug use (Carroll 2002). CBT focuses on treating substance abuse as a learned behavior that can be modified by fostering the motivation for drug abstinence, coping with drug cravings, and enhancing drug refusal skills (Carroll et al. 1994). Components of CBT include a functional analysis of drug use in which the patient identifies thoughts, feelings, and circumstances before and after drug use and skills training through which subjects learn strategies for modifying these behaviors, moods, or cognitions. CBT has proven efficacy in the treatment of drug-dependent populations (Covi et al. 2002; Maude-Griffin et al. 1998) and may have long-term durability in promoting drug abstinence (Carroll et al. 1994).

In contingency management, patients receive incentives or rewards for meeting addiction treatment goals (e.g., negative urine drug screen). Contingency management is based on operant conditioning in which behavior that is followed by positive consequences is more likely to be repeated (Carroll and Onken 2005). Several studies utilizing contingency management have demonstrated the efficacy of voucher-based incentives contingent on the patient providing a drug-free urine sample in reducing drug use, enhancing treatment retention, and maintaining cocaine abstinence (Higgins et al. 2000, 2003; Petry et al. 2004).

Twelve-Step recovery programs such as Alcoholics Anonymous are spiritually based in which drug-dependent individuals relinquish power over their addiction by yielding to a higher power. The literature contains limited evidence supporting the efficacy of 12-Step programs; however, 12-Step group participation in a given month predicted less cocaine use in the next month, and patients who increased their 12-Step group participation during the first 3 months of treatment had significantly less cocaine use and lower addiction-related functional impairments (R. D. Weiss et al. 2005).

Exploring the neural basis of response to extant addiction therapies arguably represents the most impacting future area of neuroscientific exploration targeting the reduction of the occurrence and costs of drug addiction.

FUTURE DIRECTIONS

The immense social, economic, and public health costs of drug abuse and addiction have been little checked by government interdiction policies. The "war on drugs" would be unquestionably advanced by programs of evidence-based prevention and treatment enabled by a more concise and comprehensive understanding of the neurobiology of the stages of the drug addiction process. Such an understanding demands the merger of the fields of social, affective, cognitive, cultural, behavioral, and molecular neuroscience to address the many and diverse driving mechanisms behind this complex process. In this chapter, the specific areas of emphasis on the neurobiology of the addiction process reflect not only a review of the corpus of relevant research findings but also the authors' opinions as to the needed areas of neuroscientific investigation from which a comprehensive and translationally significant understanding of the addiction process would be derived. Defining the influence of differences due to sex or to racial or ethnic background on the neurobiology of drug addiction is deemed imperative. Defining the neurobiology of largely neglected areas of crime and violence related to drug addiction and of response to addiction behavioral therapies is also of high priority. Innovative research approaches to treatment such as the exploration of the use of neurofeedback supported by real-time fMRI (deCharms et al. 2005; Weiskopf et al. 2004) of responses to relapse precipitants are needed. Much has been learned but much more research knowledge is needed to enable science, rather than interdiction policies, to lead the "war on drugs."

Chapter 50. Neurobiology of Eating Disorders

NEUROBIOLOGY OF EATING DISORDERS: INTRODUCTION

Anorexia nervosa (AN) and bulimia nervosa (BN) are disorders characterized by aberrant patterns of feeding behavior and weight regulation and disturbances in attitudes and perceptions toward body weight and shape. The distinguishing features of AN are an inexplicable fear of weight gain, unrelenting obsession with fatness, and extreme cachexia, to which the person appears strikingly indifferent. In BN, the differentiating characteristics are binge eating of variable frequency and intensity, usually emerging after a period of dieting and which may or may not have been associated with weight loss, and either self-induced vomiting or some other means of compensation for the excess of food that is consumed. Unlike in AN, weight does not decrease to dangerously low levels. In most people affected with BN, feeding patterns are disrupted and satiety may be impaired. However, although abnormally low body weight is an exclusion for the diagnosis of BN, a significant proportion of persons affected with this illness have a prior history of AN (Eddy et al. 2007).

AN and BN are cross-transmitted in families (Strober et al. 2000), often transform from one subtype to another over the course of the illness (Eddy et al. 2002; Milos et al. 2005), and share common traits and liability factors (Lilenfeld et al. 2000). Moreover, studies in the literature have often not clearly distinguished subtypes. In addition, state-related influences of malnutrition and weight loss (which tend to be worse in AN) have confounded symptoms and neurobiological measures. Thus, as we move through this chapter, rather than dividing our discussion of the two conditions along strictly categorical lines, we will highlight where they overlap and how they diverge.

The clinical distinction between AN and BN of obvious importance is that of emaciation, and while temperamental features of inhibition, restraint, and conformity are especially prominent in AN (Strober 1980), there are many areas of overlap and commonality. Persons with either condition have pathological overconcern with weight and shape, and common to both AN and BN are low self-esteem, perfectionism, depression, and anxiety (Fairburn et al. 1997, 1999). The diagnostic labels are misleading, too, as individuals with AN rarely have complete suppression of appetite but rather exhibit a motivated, and more often than not ego-syntonic, resistance to feeding drives while eventually becoming preoccupied with food and eating rituals to the point of obsession. Similarly, persons with BN, rather than suffering from a primary pathological drive to overeat, have a seemingly relentless drive to restrain their food intake, an extreme fear of weight gain, and a distorted view of their actual body size and shape. Loss of control of normative feeding patterns usually occurs intermittently and typically only some time after the onset of dieting behavior. Furthermore, episodes of binge eating ultimately develop in a significant proportion of people with AN (Halmi et al. 1991), and some 3%–5% of those starting out with BN will eventually develop AN (Fichter and Quadflieg 2007; Milos et al. 2005). Thus, because restrained eating behavior and dysfunctional cognitions relating weight and shape to self-concept are shared by patients with both of these syndromes, and because diagnostic crossover is not unusual, it has been argued that AN and BN share at least some risk and liability factors in common.

The etiology of AN and BN is presumed to be complex and multiply influenced by developmental, social, and biological processes (Treasure and Campbell 1994), the exact nature of which remain

poorly understood. Certainly, cultural attitudes toward standards of physical attractiveness have relevance, but it is unlikely that sociocultural influences in pathogenesis are preeminent. First, dieting behavior and the drive toward thinness are unusually common in industrialized countries throughout the world, yet AN and BN affect only an estimated 0.3%–0.7%, and 1.7%–2.5%, respectively, of females in the general population. Moreover, numerous, seemingly unambiguous descriptions of AN date from the middle of the nineteenth century (Treasure and Campbell 1994), suggesting that factors other than the modern social milieu play a more powerful causal role. Second, these syndromes, AN in particular, have a relatively stereotypical clinical presentation, sex distribution, and age at onset, supporting the plausibility of intrinsic biological vulnerabilities.

CLINICAL PHENOMENOLOGY AND DISEASE COURSE

Following the points above, variations in feeding behavior have been the basis for subdividing AN into diagnostic subgroups that have been shown to differ in other psychopathological characteristics (Garner et al. 1985). In the restricting subtype of AN, subnormal body weight is sustained by unremitting food avoidance, whereas in the bulimic subtype, there is comparable weight loss and malnutrition, yet the illness course is punctuated by intermittent episodes of binge eating. Interestingly, individuals with this binge subtype exhibit other dyscontrol phenomena, including histories of self-harm, affective and behavioral disorder, substance abuse, and overt family conflict in comparison to those with the restricting subtype. Regardless of subtype, individuals with AN are characterized by marked perfectionism, harm avoidance, low novelty seeking, conformity, and obsessionality, most of which appear in advance of the onset of weight loss and which tend to persist even after long-term weight recovery, indicating that they are not merely epiphenomena of acute malnutrition or disordered eating behavior (Casper 1990; Srinivasagam et al. 1995; Strober 1980).

Individuals with BN remain at normal body weight, although many aspire to preferred weights far below the range of normalcy for their age and height. The core features of BN include repeated episodes of binge eating followed by compensatory self-induced vomiting, laxative abuse, or pathologically extreme exercise, as well as abnormal concern with weight and shape. DSM-IV-TR (American Psychiatric Association 2000) specifies a distinction within this group between those individuals with BN who engage in self-induced vomiting or laxative, diuretic, or enema abuse (purging type) and those who exhibit other forms of compensatory action such as fasting or exercise (nonpurging type). Beyond these differences, it has been speculated (Vitousek and Manke 1994) that there are two clinically divergent subgroups of individuals with BN: a so-called multi-impulsive type in which bulimia occurs in conjunction with more pervasive difficulties in behavioral self-regulation and affective instability, and a second type whose distinguishing features include self-effacing behaviors, dependence on external rewards, and extreme compliance. Individuals with BN of the multi-impulsive type are far more likely to have histories of substance abuse, and they characteristically display other impulse-control problems, such as shoplifting and self-injurious behaviors. Considering these differences, it has been postulated that multi-impulsive BN individuals rely on binge eating and purging as a means of regulating intolerable states of tension, anger, and fragmentation, whereas individuals of the latter type have binge episodes precipitated through dietary restraint, with compensatory behaviors maintained through reduction of guilty feelings associated with fears of weight gain.

For most who are affected, AN is a protracted disease; roughly 50%–70% of affected individuals will eventually have reasonably complete resolution of the illness, but the time to achieve this state is, for the most part, quite lengthy. Thus, a significant proportion of persons with AN express subthreshold levels of illness that wax and wane in severity long into adulthood, with some individuals having a chronic, wholly unremitting course, and with 5%–10% of those affected eventually dying from complications of the disease or from suicide. For BN, the course trajectory is somewhat different. Rather than continuously presenting symptoms that persist for years without periods of full recovery,

follow-up studies of 5–10 years in duration show that 50% of BN individuals have recovered while nearly 20% continue to meet full syndromal criteria for BN (Keel and Mitchell 1997). The typical course pattern is one of unpredictable vacillation between periods of restricted food intake, gorging, and vomiting, one that will wax and wane over the course of several years.

FAMILY EPIDEMIOLOGY AND GENETICS

Family and Twin Studies

Findings from systematic case–control studies (Lilenfeld et al. 1998; Strober et al. 2000) suggest a 7- to 12-fold increase in the prevalence of AN and BN in relatives of eating disorder probands compared with never-ill control subjects. These significant familial recurrence risks of AN and BN provide impressive evidence of the transmissibility of both phenotypes.

Twin studies of AN and BN are still few in number, but evidence to date suggests greater resemblance among monozygotic twins relative to dizygotic twins for both AN and BN, with 58%–76% of the variance in AN (Klump et al. 2001a; Wade et al. 2000) and 54%–83% of the variance in BN (Bulik et al. 1998; Kendler et al. 1991) accounted for by additive genetic factors, estimates that accord with those found in studies of schizophrenia and bipolar disorder.

In accord with previous discussion of clinical overlap and longitudinal continuities, AN and BN appear to have familial liabilities shared in common. Convergent findings from family and twin studies indicate an increased coaggregation of AN and BN among relatives of AN and BN probands (Lilenfeld et al. 1998; Strober et al. 2000; Walters and Kendler 1995), suggesting both unique and common familially transmitted causative elements.

In this vein, the transmitted liability to eating disorders may express a more diffuse phenotype of continuous traits. In support of this model of transmitted vulnerability is strong evidence of the heritability of disordered eating attitudes, weight preoccupation, dissatisfaction with weight and shape, dietary restraint, binge eating, and self-induced vomiting in the general population, with 32%–72% of the variance in these behavioral features potentially accounted for by additive genetic factors (Klump et al. 2000b; Rutherford et al. 1993; Sullivan et al. 1998; Wade et al. 1998, 1999). In addition, subthreshold forms of eating disorders have also been shown to coaggregate in families with full-syndrome AN and BN (Strober et al. 2000), lending added support to the idea of a continuum of transmitted liability in at-risk families manifesting a broad spectrum of eating disorder phenotypes.

That risk is mediated by developmental processes is supported by recent data (Klump et al. 2000b, 2007) from the Minnesota Twin Family Study, which examined the effects of age and pubertal status on the heritability of eating attitudes and behaviors. In the first of these studies (Klump et al. 2000b), the differential influence of genetic versus environmental effects was compared in 11-year-old twins (n = 680) and 17-year-old twins (n = 602). Whereas genetic influence on weight preoccupation and overall eating pathology was negligible for the younger age cohort, more than half of the variance in these attitudes and behaviors could be accounted for by genetic factors in the 17-year-old cohort. The follow-up analysis of the data set (Klump et al. 2007), in which the younger cohort was subdivided by pubertal status, revealed a more powerful effect of puberty than of age per se, suggesting a potential role of pubertal ovarian steroid activity in activating genes of etiological importance in eating disorders.

Genetic Findings

Comprehensive genomic studies of AN and BN remain sparse. The first genomewide search for potential disease susceptibility genes in AN (Kaye et al. 2000) was an international collaboration that applied a nonparametric allele-sharing linkage analysis to data from 192 kindreds with at least one affected relative pair with AN and related eating disorders, including BN (Grice et al. 2002). Although evidence for linkage in the entire sample was negligible, an analysis using a narrow affection status

model composed only of relatives with restricting-type AN generated a peak multipoint nonparametric linkage score of 3.45 in the 1p33–36 region. In a further analysis (B. Devlin et al. 2002), two variables incorporated as covariates into the linkage analysis—drive for thinness and obsessionality—yielded several regions of suggestive linkage, one close to genomewide significance on another region of chromosome 1 (logarithm of odds [LOD] score = 3.46). Although considered preliminary, these initial findings suggest genetic heterogeneity in eating disorders and the potential value of applying more refined genomic analyses on large samples of AN subjects.

A growing number of studies using a case–control design have examined the potential association of various candidate genes with AN and BN (see reviews by Klump et al. 2001b; Tozzi et al. 2002). Evidence linking AN and BN to monoamine functioning (see below) has led researchers to target serotonin-related (5-HT_{2A}, 5-$HT1_D\beta$, 5-HTT, 5-HT_7, tryptophan hydroxylase receptor) and dopamine-related (D_3, D_4) genes, but findings to date have been inconsistent or negative. Our group has followed up the initial report of linkage of restricting AN to the chromosome 1p region (Grice et al. 2002), with evidence of significant association with two genes under this linkage peak, the 5-HT_{1D} (HTR1D) and delta opioid (OPRD1) receptors, along with the dopamine receptor on chromosome 11 (Bergen et al. 2003), and a British group has reported a confirmation of the HTR1D and OPRD1 association in a case–control study (Brown et al. 2007).

The presumptive role of atypicalities in feeding and energy expenditure in the pathophysiology of AN and BN has led researchers to examine genes related to these processes. Findings suggest possible associations between AN and the UCP-2/UCP-3 gene (Campbell et al. 1999), the estrogen receptor β gene (Rosenkranz et al. 1998), and the gene for agouti-related protein (Vink et al. 2001), but here, too, no consistently replicated evidence for association with either AN or BN has accrued to date.

Association studies of BN are scant, with one study (Bulik et al. 2003) reporting significant linkage on chromosome 10p and another (Steiger et al. 2005) suggesting that the short (S) allele in the promoter region of the 5-HTT gene may confer risk for affective and behavior dysregulation among persons with BN.

In general, the results in this area to date argue convincingly for the importance of characterizing the latent phenotypic structure underlying these conditions and the application of more refined covariate and quantitative trait locus models of genomewide association and linkage analyses (Bacanu et al. 2005; Bulik et al. 2005) in the search for genes of potential relevance.

Associations With Other Behavioral Phenotypes

As noted, a variety of behavioral symptoms and traits occurs prominently in people with AN. Accordingly, several family and twin studies have examined the covariation between eating disorders and various other psychiatric conditions. These studies have been reviewed in detail (Lilenfeld et al. 1998; Strober et al. 2000). With regard to major affective illness, studies of AN probands have yielded familial risk estimates in the range of 7%–25%, with relative risk estimates in studies employing healthy control subjects in the range of 2.1–3.4. Likewise, studies of BN probands have shown, with rare exception, that their first-degree relatives are several times more likely to develop affective disorders than are relatives of control subjects (Mangweth et al. 2003). Several recent twin and family studies support this conclusion, as both found evidence for shared as well as unique genetic influences on major depression in both AN and BN (Kendler et al. 1995; Wade et al. 2000). In short, and lending further support to the notion of shared liability in AN and BN, both conditions often co-occur with major mood/anxiety disorders, which likewise cluster in family members.

An interesting potential discontinuity is with regard to substance use disorders. Although several studies (Kaye et al. 1996; Schuckit et al. 1996) found no evidence of cross-transmission of BN and substance use disorder in families, and twin data (Kendler et al. 1995) have shown that the genes influencing susceptibility to alcoholism were independent of those underlying BN risk, one recent

study suggests some sharing of genetic influences that confer risk to drug use disorder and BN (Baker et al. 2007).

Independent familial transmission of obsessive-compulsive disorder (OCD) and both AN and BN was recently found in a controlled family study of eating disorders (Lilenfeld et al. 1998). By contrast, shared transmission was found between broadly defined AN and BN and various anxiety disorder phenotypes (Miller et al. 1998), and a genetic correlation has been reported between BN and both phobia and panic disorder (Kendler et al. 1995). Preliminary data also suggest common familial transmission of AN and obsessive-compulsive personality disorder (OCPD) (Lilenfeld et al. 1998; Strober et al. 2007). These results point in the general direction of linking genetic risk factors for various anxiety-related phenomena to susceptibility to eating disorders.

NEUROBIOLOGY OF EATING DISORDERS

Overview

The assumed absence of confounding nutritional influences in recovered eating-disordered women suggests that persistent psychobiological abnormalities and atypical behaviors might be trait related and etiopathogenetic. Investigators (Casper 1990; Kaye et al. 1998; Srinivasagam et al. 1995; Strober 1980; Wagner et al. 2006a) have found that many women who were in long-term recovery from AN and BN have persistence of anxiety, harm avoidance, perfectionism, and obsessional behaviors. Moreover, persons recovered from AN and BN often express associated eating disorder psychological symptoms, including ineffectiveness, drive for thinness, and significant psychopathology related to eating habits. Therefore, persistence of certain features after recovery raises the question of whether a disturbance of such behaviors may in fact occur premorbidly and contribute to the pathogenesis of AN and BN.

The role of biology in the etiology of AN has been proposed for many decades (Treasure and Campbell 1994). New understandings of the neurotransmitter modulation of appetitive behaviors have raised the question of whether such disturbances cause eating disorders (Fava et al. 1989; Morley and Blundell 1988). Moreover, technologies that permit direct measurement of complex brain functions and their relationships to behavior are shedding new light on the pathophysiology of these disorders.

Imaging Studies

It is well known that ill subjects with AN have enlarged ventricles and sulci widening (see review by Ellison and Foong 1998). Proton magnetic resonance spectroscopy (^{1}H-MRS) revealed reduced lipid signals in the frontal white matter and occipital gray matter and was associated with decreased body mass index (BMI) (Roser et al. 1999). Whether these abnormalities persist to a lesser degree after weight restoration is less certain, since some studies show persistent alterations (Katzman et al. 1996) but other studies show normalization of gray and white matter after recovery in AN and BN (Wagner et al. 2006b).

I. Gordon et al. (1997) found that 13 of 15 ill AN subjects studied had unilateral temporal lobe hypoperfusion that persisted after weight restoration. A later study (Chowdhury et al. 2001) found that adolescent AN subjects had unilateral temporoparietal and frontal lobe hypoperfusion. Kuruoglu et al. (1998), studying two ill AN patients, found bilateral hypoperfusion in frontal, temporal, and parietal regions that normalized after 3 months of remission. Takano et al. (2001) found hypoperfusion in the medial prefrontal cortex and anterior cingulate and hyperperfusion in the thalamus and amygdalo–hippocampal complex. Rastam et al. (2001) found temporoparietal and orbitofrontal hypoperfusion in ill and recovered AN subjects. Fewer studies have assessed glucose metabolism using positron emission tomography (PET). Delvenne et al. (1995) studied ill AN subjects who, in comparison with control subjects, had frontal and parietal hypometabolism that normalized with weight gain. More recently, single photon emission computed tomography (SPECT) studies of

resting blood flow in restricting-type AN patients before and after weight restoration have suggested reduced blood flow in the anterior cingulate in both state conditions, compared with control subjects (Kojima et al. 2005a). Few brain imaging studies have examined BN subjects, but findings from several groups (Andreason et al. 1992; Delvenne et al. 1999; Nozoe et al. 1995; Wu et al. 1990) have raised the possibility of frontal or temporal alterations and hemispheric asymmetry.

In summary, these studies show temporal, frontal, parietal, and cingulate region disturbances in AN subjects, both when ill and after various degrees of recovery. Although these studies show some consistency, particularly in terms of temporal involvement, it should be noted that the numbers of subjects in each study tended to be small, and definitions of subgroups and states of illness were often inconsistent. Small sample sizes and irregular definitions make it difficult to know whether these are lateralizing findings or there are differences between subtypes of eating disorders. The meaning of these findings is open to interpretation. At the least, they suggest that regions of the brain involved in the modulation of mood, cognition, impulse control, and decision making may be altered in AN and BN.

Body Image Distortion

A most puzzling symptom of AN is the severe and intense body image distortion, in which emaciated individuals perceive themselves as fat. Wagner et al. (2003) confronted AN patients and age-matched healthy control subjects with their own digitally distorted body images as well as images of a different person using a computer-based video technique. These studies reported a hyperresponsiveness in brain areas belonging to the frontal visual system and the attention network (Brodmann area 9) as well as the inferior parietal lobule (Brodmann area 40), including the anterior part of the intraparietal sulcus. Bailer et al. (2004) reported negative relationships between 5-HT_{2A} receptor activity and the Eating Disorder Inventory Drive for Thinness scale in the left parietal cortex and other regions. Uher et al. (2005) showed a cohort of women (9 with BN, 13 with AN, and 18 healthy controls) line drawings of female bodies and found that the subjects with eating disorders had reduced hemodynamic response in the right parietal (Brodmann area 40) cortex. It is intriguing to raise the possibility that parietal disturbances may contribute to body image distortion. Theoretically, body image distortion might be related to the syndrome of neglect (Mesulam 1981), which may be coded in parietal, frontal, and cingulate regions that assign motivational relevance to sensory events. It is well known that lesions in the right parietal cortex not only may result in denial of illness or anosognosia, somatoparaphrenia, and numerous misidentification syndromes but also may produce experiences of disorientation of body parts and body image distortion. It has long been recognized that the parietal cortex mediates perceptions of the body and its activity in physical space (Gerstmann 1924). Recent work extends this concept to suggest that the parietal lobe contributes to the experience of being an "agent" of one's own actions (Farrar et al. 2003).

Appetitive Regulation

Individuals with AN and those who have had lifetime diagnoses of both AN and BN (AN-BN) tend to have negative mood states and dysphoric temperament. There is evidence that there is a dysphoria reducing character to dietary restraint in AN (Kaye et al. 2003; Strober 1995; Vitousek and Manke 1994) and binge/purge behaviors in BN (Abraham and Beaumont 1982; Johnson and Larson 1982; Kaye et al. 1986). This would suggest some interaction between pathways regulating appetitive behaviors and emotions. In fact, imaging studies support this hypothesis. When emaciated and malnourished AN individuals are shown pictures of food, they display abnormal activity in the insula and orbitofrontal cortex as well as in mesial temporal, parietal, and anterior cingulate cortex (Ellison et al. 1998; C. M. Gordon et al. 2001; Naruo et al. 2000; Nozoe et al. 1993, 1995; Uher et al. 2004). In addition, studies using SPECT, PET (with ^{15}O), or functional magnetic resonance imaging (fMRI) found that when subjects ill with AN ate food or were exposed to food, they showed activation in temporal

regions and often experienced increased anxiety (Ellison et al. 1998; C. M. Gordon et al. 2001; Naruo et al. 2000; Nozoe et al. 1993). Those results could be consistent with anxiety provocation and related amygdala activation and with the notion that the emotional value of an experience is stored in the amygdala (LeDoux 2003). Uher et al. (2003) used pictures of food and nonfood aversive emotional stimuli and fMRI to assess ill and recovered AN subjects. Food stimulated medial prefrontal and anterior cingulate cortex in both recovered and ill AN subjects but lateral prefrontal regions only in the recovered group. The prefrontal cortex, anterior cingulate cortex, and cerebellum were more highly activated after food intake in recovered AN subjects compared with both control subjects and subjects chronically ill with AN. This finding suggested that higher anterior cingulate cortex and medial prefrontal cortex activity in both ill and recovered AN women compared with controls may be a trait marker for AN.

A recent study (Wagner et al. 2008) used fMRI to investigate the effect of administration of nutrients. In comparison with controls, recovered AN subjects had a significantly reduced fMRI signal response to the blind administration of sucrose or water in the insula, anterior cingulate, and striatal regions. For controls, self-ratings of pleasantness of the sugar taste were positively correlated to the signal response in the insula, anterior cingulate, and ventral and dorsal putamen. By contrast, recovered AN individuals failed to show any relationship in these regions to self-ratings of pleasant response to a sucrose taste. A large literature shows that the anterior insula and associated gustatory cortex respond not only to the taste and physical properties of food but also to its rewarding properties (O'Doherty et al. 2001; Schultz et al. 2000; Small et al. 2001). Insular inputs to the ventrolateral striatum are hypothesized to mediate behaviors involving eating, particularly of highly palatable, high-energy foods (Kelley et al. 2002). AN subjects tend to avoid high-calorie, high-palatability food. In theory, this is consistent with abnormal responses of insula–striatal circuits that are hypothesized to mediate behavioral responses to the incentive value of food.

Implications

Do individuals with AN have an insular disturbance specifically related to gustatory modulation or a more generalized disturbance related to the integration of interoceptive stimuli? This is of interest because the insula is thought to play an important role in processing interoceptive information (Craig 2002). Interoception, which can be defined as the sense of the physiological condition of the entire body, has long been thought to be critical for self-awareness, because it provides the link between cognitive and affective processes and the current body state. Aside from taste, interoceptive information includes sensations such as temperature, touch, muscular and visceral sensations, vasomotor flush, air hunger, and others (Paulus and Stein 2006). It remains to be determined which altered insula function contributes to symptoms in AN, such as disturbed self-awareness (e.g., ego-syntonic denial and impaired central coherence), lack of recognition of the effects of starvation and pain tolerance, and perhaps body image distortions. Finally, it is possible that AN individuals have reduced insula and striatal "reward" response to palatable foods. Because food may lack reward value or may be paradoxically anxiolytic for individuals with AN, they may not be able to respond to normal homeostatic mechanisms that drive hunger, thus becoming emaciated.

STUDIES OF NEUROTRANSMITTERS

Neuropeptides

The past decade has witnessed accelerating basic research on the role of neuropeptides in the regulation of feeding behavior and obesity. The mechanisms for controlling food intake involve a complicated interplay between peripheral systems (including gustatory stimulation, gastrointestinal peptide secretion, and vagal afferent nerve responses) and central nervous system (CNS) neuropeptides and/or monoamines. Thus, studies in animals show that neuropeptides—such as cholecystokinin, the endogenous opioids (e.g., β-endorphin), and neuropeptide Y—regulate the rate,

duration, and size of meals, as well as macronutrient selection (Morley and Blundell 1988; Schwartz et al. 2000). In addition to regulating eating behavior, a number of CNS neuropeptides participate in the regulation of neuroendocrine pathways. Thus, clinical studies have evaluated the possibility that CNS neuropeptide alterations may contribute to dysregulated secretion of gonadal hormones, cortisol, thyroid hormones, and growth hormone in the eating disorders (Jimerson et al. 1998; Stoving et al. 1999).

While there are relatively few studies to date, most of the neuroendocrine and neuropeptide alterations apparent during symptomatic episodes of AN and BN tend to normalize after recovery. This observation suggests that most of the disturbances are consequences rather than causes of malnutrition, weight loss, and altered meal patterns. Still, an understanding of these neuropeptide disturbances may shed light on why many people with AN or BN cannot easily "reverse" their illness. In AN, malnutrition may contribute to a downward spiral sustaining and perpetuating the desire for more weight loss and dieting. Symptoms such as increased satiety, obsessions, and dysphoric mood may be exaggerated by these neuropeptide alterations and thus contribute to the downward spiral. Additionally, mutual interactions between neuropeptide, neuroendocrine, and neurotransmitter pathways may contribute to the constellation of psychiatric comorbidity often observed in these disorders. Even after weight gain and normalized eating patterns, many individuals who have recovered from AN or BN have physiological, behavioral, and psychological symptoms that persist for extended periods of time. Menstrual cycle dysregulation, for example, may persist for some months after weight restoration. In the following sections we provide a brief overview of studies of neuropeptides in AN and BN.

Corticotropin-Releasing Hormone

When underweight, patients with AN have increased plasma cortisol secretion that is thought to be at least in part a consequence of hypersecretion of endogenous corticotropin-releasing hormone (CRH) (Gold et al. 1986; Kaye et al. 1987b; Licinio et al. 1996; Walsh et al. 1987). Given that the plasma and cerebrospinal fluid (CSF) measures return toward normal, it appears likely that activation of the hypothalamic-pituitary-thyroid axis is precipitated by weight loss. The observation of increased CRH activity is of great theoretical interest in AN, given that intracerebroventricular CRH administration in experimental animals produces many of the physiological and behavioral changes associated with AN, including markedly decreased eating behavior (Glowa and Gold 1991).

Opioid Peptides

Studies in laboratory animals raise the possibility that altered endogenous opioid activity might contribute to pathological feeding behavior in eating disorders because opioid agonists generally increase, and opioid antagonists decrease, food intake (Morley et al. 1985). State-related reductions in concentrations of CSF β-endorphin and related opiate concentrations have been found in both underweight AN and ill BN subjects (Brewerton et al. 1992; Kaye et al. 1987a; Lesem et al. 1991). In contrast, using the T lymphocyte as a model system, Brambilla et al. (1995a) found elevated β-endorphin levels in AN, although the levels were normal in BN. If β-endorphin activity is a facilitator of feeding behavior, then reduced CSF concentrations could reflect decreased central activity of this system, which then maintains or facilitates inhibition of feeding behavior in the eating disorders.

Neuropeptide Y and Peptide YY

Neuropeptide Y (NPY) and peptide YY (PYY) are of considerable theoretical interest, because they have potent endogenous effects on feeding behavior within the CNS (Kalra et al. 1991; Morley et al. 1985; Schwartz et al. 2000). Underweight individuals with AN have been shown to have elevated CSF levels of NPY but normal levels of PYY (Kaye et al. 1990b). Clearly, elevated NPY does not result in increased feeding in underweight AN individuals; however, the possibility that increased NPY activity underlies the obsessive and paradoxical interest in dietary intake and food preparation is a hypothesis

worth exploring. On the other hand, CSF levels of NPY and PYY have been reported to be normal in women with BN when measured while subjects were acutely ill. Although levels of PYY increased above normal when subjects were reassessed after 1 month of abstinence from bingeing and vomiting, levels of the peptides were similar to control values in long-term recovered individuals (Gendall 1999).

More recently, it has been reported that the plasma concentration of NPY was lower in patients with AN than in control subjects, whereas patients with BN had elevated NPY levels (Baranowska et al. 2000). Other data indicate that basal plasma PYY levels in AN are similar to or elevated in comparison with control values, with variability in postprandial PYY responses also noted across studies (Germain et al. 2007; Misra et al. 2006; Nakahara et al. 2007; Otto et al. 2007; Stock et al. 2005). Initial studies indicate that basal plasma PYY levels in BN are similar to control values but that the postprandial response is significantly blunted in the patient group (Kojima et al. 2005b; Monteleone et al. 2005). Additional research will be needed to assess the potential behavioral correlates of these findings.

Cholecystokinin

Cholecystokinin (CCK) is a peptide secreted by the gastrointestinal system in response to food intake. Release of CCK is thought to be one means of transmitting satiety signals to the brain by way of vagal afferents (Gibbs et al. 1973). In parallel to its role in satiety in rodents, exogenously administered CCK reduces food intake in humans. The preponderance of data suggests that patients with BN, in comparison with control subjects, have diminished release of CCK following ingestion of a standardized test meal (M. J. Devlin et al. 1997; Geracioti and Liddle 1988; Phillipp et al. 1991; Pirke et al. 1994). Measurements of basal CCK values in blood lymphocytes and in CSF also appear to be decreased in patients with BN (Brambilla et al. 1995a; Lydiard et al. 1993). It has been suggested that the diminished CCK response to a meal may play a role in diminished postingestive satiety observed in BN. The CCK response in bulimic patients was found to return toward normal following treatment (Geracioti and Liddle 1988).

Studies of CCK in AN have yielded less consistent findings. Some studies have found elevations in basal levels of plasma CCK (Phillipp et al. 1991; Tamai et al. 1993), as well as increased peptide release following a test meal (Harty et al. 1991; Phillipp et al. 1991). One study found that blunting of CCK response to an oral glucose load normalized in AN patients after partial restoration of body weight (Tamai et al. 1993). Other studies have found that measures of CCK function in AN were similar to or lower than control values (Baranowska et al. 2000; Brambilla et al. 1995b; Geracioti et al. 1992; Pirke et al. 1994). Further studies are needed to evaluate the relationship between altered CCK regulation and other indices of abnormal gastric function in symptomatic BN and AN patients (Geliebter et al. 1992).

Leptin

Leptin, the protein product of the *ob* gene, is secreted predominantly by adipose tissue cells and acts in the CNS to decrease food intake, thus regulating body fat stores. In rodent models, defects in the leptin coding sequence resulting in leptin deficiency or defects in leptin receptor function are associated with obesity. In humans, serum and CSF concentrations of leptin are positively correlated with fat mass in individuals across a broad range of body weight. Obesity in humans is not thought to be a result of leptin deficiency per se, although rare genetic deficiencies in leptin production have been associated with familial obesity.

Underweight patients with AN have consistently been found to have significantly reduced serum leptin concentrations in comparison with normal-weight control subjects (Baranowska et al. 2001; Grinspoon et al. 1996; Hebebrand et al. 1995; Mantzoros et al. 1997). Based on studies in laboratory animals, it has been suggested that low leptin levels may contribute to amenorrhea and other hormonal changes in the disorder (Mantzoros et al. 1997). Although the reduction in fasting serum

leptin levels in AN is correlated with reduction in BMI, there has been some discussion of the possibility that leptin levels in patients with AN may be higher than expected based on the extent of weight loss (Frederich et al. 2002; Jimerson 2002). Mantzoros et al. (1997) reported an elevated CSF-to-serum leptin ratio in AN patients compared with control subjects, suggesting that the proportional decrease in leptin levels with weight loss is greater in serum than in CSF. A longitudinal investigation during refeeding in patients with AN showed that CSF leptin concentrations reach normal values before full weight restoration, possibly as a consequence of the relatively rapid and disproportionate accumulation of fat during refeeding (Mantzoros et al. 1997). This finding led the authors to suggest that premature normalization of leptin concentration might contribute to difficulty in achieving and sustaining a normal weight in AN. Plasma and CSF leptin levels appear to be similar to control values in long-term recovered AN subjects (Gendall 1999).

More recent studies indicate that patients with BN, in comparison with carefully matched control subjects, have significantly decreased leptin concentrations in serum samples obtained after an overnight fast (Baranowska et al. 2001; Brewerton et al. 2000). Initial findings in individuals who have achieved sustained recovery from BN, compared with control subjects with closely matched percentages of body fat, suggest that serum leptin levels remain decreased. This finding may be related to evidence for a persistent decrease in activity in the hypothalamic-pituitary-thyroid axis in long-term recovered BN individuals. These alterations could be associated with decreased metabolic rate and a tendency toward weight gain, contributing to the preoccupation with body weight characteristic of BN.

Ghrelin

Intracerebroventricular injections of the gut-related peptide ghrelin strongly stimulated feeding in rats and increased body weight gain. When administered to healthy human volunteers, ghrelin results in increased hunger and food intake (Wren et al. 2001). In addition, it has been reported that fasting plasma ghrelin concentrations in humans are negatively correlated with BMI (Shiiya et al. 2002; Tanaka et al. 2002), percentage body fat, and fasting leptin and insulin concentrations (Tschop et al. 2001). As recently reviewed, a number of studies have shown elevation in circulating ghrelin levels in AN, with a return to normal levels as patients regain weight (Jimerson and Wolfe 2006). Further research is needed to explore the possible existence of ghrelin resistance in cachectic states related to the eating disorders.

Studies comparing fasting plasma ghrelin concentrations in patients with BN and healthy controls have yielded variable results (Jimerson and Wolfe 2006). It is of interest, however, that the postprandial decrease in ghrelin levels appears to be blunted in patients with BN (Kojima et al. 2005b; Monteleone et al. 2005), consistent with other evidence for diminished satiety responses in the disorder.

Monoamine Systems

There is an abundance of evidence that individuals with AN and BN have disturbances of monoamine function in the ill state. While less well studied, monoamine disturbances appear to persist after recovery.

Dopamine

Altered dopamine activity has been found among ill AN and BN individuals. Homovanillic acid (HVA), the major metabolite of dopamine in humans, was decreased in CSF of underweight AN subjects (Kaye et al. 1984). Although ill subjects with BN, as a group, have normal CSF levels of HVA, several studies have shown significant reductions of CSF HVA levels in BN patients with high binge frequency (Jimerson et al. 1992; Kaye et al. 1990a). Individuals with AN have altered frequency of functional polymorphisms of dopamine D_2 receptor genes that might affect receptor transcription and translation

efficiency (Bergen et al. 2005) and impaired visual discrimination learning (Lawrence 2003), a task thought to reflect dopamine signaling function. CNS dopamine metabolism may explain differences in symptoms between AN, AN-BN, and BN subjects. Our group (Kaye et al. 1999) found that recovered AN subjects had significantly reduced concentrations of CSF HVA in comparison with recovered AN-BN or BN women. A PET imaging study (Frank et al. 2005) found recovered AN subjects had increased binding of D_2 and D_3 receptors in the anteroventral striatum. Dopamine neuronal function has been associated with motor activity (Kaye et al. 1999) and with optimal response to reward stimuli (Montague et al. 2004; Schultz 2004). Individuals with AN have stereotyped and hyperactive motor behavior and anhedonic and restrictive personalities.

Serotonin

5-HT pathways play an important role in postprandial satiety. Treatments that increase intrasynaptic 5-HT or that directly activate 5-HT receptors tend to reduce food consumption, whereas interventions that dampen 5-HT neurotransmission or block receptor activation reportedly increase food consumption and promote weight gain (Blundell 1984; Leibowitz and Shor-Posner 1986). Moreover, CNS 5-HT pathways have been implicated in the modulation of mood, impulse regulation and behavioral constraint, and obsessionality, and they affect a variety of neuroendocrine systems.

There has been considerable interest in the role that 5-HT may play in AN and BN (Brewerton 1995; Jimerson et al. 1990; Kaye and Weltzin 1991; Kaye et al. 1998; Steiger et al. 2005; Treasure and Campbell 1994). In part, this interest derives from study findings of alterations in 5-HT metabolism in AN and BN. When underweight, individuals with AN have a significant reduction in basal concentrations of the serotonin metabolite 5-hydroxyindolacetic acid (5-HIAA) in the CSF compared with healthy control subjects, as well as blunted plasma prolactin response to drugs with 5-HT activity and reduced ^{3}H-imipramine binding. Together, these findings suggest reduced serotonergic activity, although this may arise secondarily to reductions in dietary supplies of the 5-HT–synthesizing amino acid tryptophan. By contrast, CSF concentrations of 5-HIAA are reported to be elevated in long-term weight-recovered AN individuals. These contrasting findings of reduced and heightened serotonergic activity in acutely ill and long-term recovered AN individuals, respectively, may seem counterintuitive; however, since dieting lowers plasma tryptophan levels in otherwise healthy women (Anderson et al. 1990), resumption of normal eating in individuals with AN may unmask intrinsic abnormalities in serotonergic systems that mediate certain core behavioral or temperamental underpinnings of risk and vulnerability.

Considerable evidence also exists for a dysregulation of serotonergic processes in BN. Examples include blunted prolactin response to the 5-HT receptor agonists *m*-chlorophenylpiperazine (m-CPP), 5-hydroxytryptophan, and *dl*-fenfluramine and enhanced migraine-like headache response to m-CPP challenge. Acute perturbation of serotonergic tone by dietary depletion of tryptophan has been linked to increased food intake and mood irritability in individuals with BN compared with healthy control subjects. Also, as in AN, women with long-term recovery from BN have been shown to have elevated CSF concentrations of 5-HIAA as well as reduced platelet binding of paroxetine (Steiger et al. 2005).

Serotonin and Behavior

There is an extensive literature associating the serotonergic systems and fundamental aspects of behavioral inhibition (Geyer 1996; Soubrie 1986). Reduced CSF 5-HIAA levels are associated with increased impulsivity and aggression in humans and nonhuman primates, whereas increased CSF 5-HIAA levels are related to behavioral inhibition (Fairbanks et al. 2001; Westergaard et al. 2003). Thus, it is of interest that women who had recovered from AN and BN showed elevated CSF 5-HIAA concentrations. Behaviors found after recovery from AN and BN, such as obsessionality with symmetry and exactness, anxiety, and perfectionism, tend to be opposite in character to behaviors displayed by people with low 5-HIAA levels. Together, these studies contribute to a growing literature suggesting

that reduced CSF 5-HIAA levels are related to behavioral undercontrol, whereas increased CSF 5-HIAA concentrations may be related to behavioral overcontrol.

The possibility of a common vulnerability for BN and AN may seem puzzling, given the well-recognized differences in behavior in these disorders. However, studies suggest that AN and BN have a shared etiological vulnerability—that is, there is a familial aggregation of a range of eating disorders in relatives of probands with either BN or AN, and these two disorders are highly comorbid in twin studies. BN responds to 5-HT-specific medications. Few controlled trials of 5-HT-specific medication have been done in AN, and it remains uncertain whether there is a beneficial response. Both disorders have high levels of harm avoidance (Klump et al. 2000a), a personality trait hypothesized to be related to increased 5-HT activity. These data raise the possibility that a disturbance of 5-HT activity may create a vulnerability for the expression of a cluster of symptoms that are common to both AN and BN. Other factors that are *independent* of a vulnerability for the development of an eating disorder may contribute to the development of eating disorder subgroups. For example, people with restricting-type AN have extraordinary self-restraint and self-control. The risk for obsessive-compulsive *personality* disorder is elevated only in this subgroup and in their families and shows a shared transmission with restricting-type AN (Lilenfeld et al. 1998). In other words, an additional vulnerability for behavioral overcontrol and rigid and inflexible mood states, combined with a vulnerability for an eating disorder, may result in restricting-type AN.

The contribution of 5-HT to specific human behaviors remains uncertain. 5-HT has been postulated to contribute to temperament or personality traits such as harm avoidance (Cloninger 1987) and behavioral inhibition (Soubrie 1986) or to categorical dimensions such as OCD (Barr et al. 1992), anxiety and fear (Charney et al. 1990), and depression (Grahame-Smith 1992), as well as satiety for food consumption. It is possible that separate components of 5-HT neuronal systems (i.e., different pathways or receptors) are coded for such specific behaviors. However, that may not be consistent with the neurophysiology of 5-HT neuronal function.

PET Studies Using 5-HT Receptor Radioligands

The marriage of PET imaging with selective neurotransmitter radioligands has resulted in a technology permitting new insights into regional binding and specificity of 5-HT and dopamine neurotransmission in vivo in humans and their relationship to behaviors.

The 5-HT_{1A} autoreceptor is located presynaptically on 5-HT somatodendritic cell bodies in the raphe nucleus, where it functions to decrease 5-HT neurotransmission (Staley et al. 1998). High densities of postsynaptic 5-HT_{1A} exist in the hippocampus, septum, amygdala, and entorhinal and frontal cortex, where they serve to mediate the effects of released 5-HT. Studies in animals and humans implicate the 5-HT_{1A} receptor in anxiety (File et al. 2000) and depression and/or suicide (Mann 1999). Pharmacological and knockout studies implicate the 5-HT_{1A} receptor in the modulation of anxiety (Gross et al. 2002). Bailer et al. (2007) reported that ill AN individuals had a 50%–70% increase in 5-HT_{1A} receptor–binding potential in subgenual, mesial temporal, orbitofrontal, and raphe brain regions, as well as in prefrontal, lateral temporal, anterior cingulate, and parietal regions. Increased 5-HT_{1A} postsynaptic activity has been reported in ill BN subjects (Tiihonen et al. 2004). Recovered binge-eating/purging–type AN subjects and BN subjects (Bailer et al. 2005; W. Kaye, unpublished data, March 2008) showed significant (20%–40%) increases in 5-HT_{1A} receptor binding potential in these same regions compared with healthy control subjects (Bailer et al. 2005). By contrast, recovered restricting-type AN women showed no difference in 5-HT_{1A} receptor binding potential compared with control subjects (Bailer et al. 2005).

AN and BN are frequently comorbid with depression and anxiety disorders. However, reduced 5-HT_{1A} receptor binding potential has been found in ill (Drevets et al. 1999; Sargent et al. 2000) and recovered (Bhagwagar et al. 2004) depressed subjects, as well as in a primate model for depression

(Shively et al. 2006). Parsey et al. (2005) found no difference in carbonyl-^{11}C]WAY100635 binding potential in major depressive disorder, although a subgroup of never-medicated subjects had elevated carbonyl-^{11}C]WAY100635 binding potential. Recent studies have found reduced [^{11}C]WAY100635 binding potential in social phobia (Lanzenberger et al. 2007) and panic disorder (Neumeister et al. 2004). These findings suggest that AN and BN, anxiety, and depression share disturbances of common neuronal pathways but are etiologically different.

Postsynaptic 5-HT$_{2A}$ receptors, which are present at high densities in the cerebral cortex and other regions of rodents and humans (Burnet et al. 1997; Saudou and Hen 1994), are of interest because they have been implicated in the modulation of feeding and mood as well as in selective serotonin reuptake inhibitor response (Bailer et al. 2004; Bonhomme and Esposito 1998; De Vry and Schreiber 2000; Simansky 1996; Stockmeier 1997). Ill AN subjects were found to have normal 5-HT$_{2A}$ receptor binding potential values in one study (Bailer et al. 2007) and reduced binding potential in another study (Audenaert et al. 2003) in the left frontal, bilateral parietal, and occipital cortex. After recovery, individuals with restricting-type AN had reduced 5-HT$_{2A}$ receptor binding potential in mesial temporal and parietal cortical areas as well as in subgenual and pregenual cingulate cortex (Frank et al. 2002). Similarly, recovered binge-eating/purging–type AN women had reduced 5-HT$_{2A}$ receptor binding potential in the left subgenual cingulate, left parietal, and right occipital cortex (Bailer et al. 2004), and recovered BN women had reduced [^{18}F]altanserin binding potential relative to controls in the orbitofrontal region (Kaye et al. 2001).

The PET imaging studies in ill and recovered AN and BN subjects described above found significant correlations between harm avoidance and binding for the 5-HT$_{1A}$, 5-HT$_{2A}$, and dopamine D$_2$/D$_3$ receptors in mesial temporal and other limbic regions. Bailer et al. (2004) found that recovered AN-BN subjects showed a positive relationship between [^{18}F]altanserin binding potential in the left subgenual cingulate and mesial temporal cortex and harm avoidance. For ill AN subjects, [^{18}F]altanserin binding potential was positively related to harm avoidance in the supragenual cingulate, frontal, and parietal regions. 5-HT$_{2A}$ receptor binding and harm avoidance were shown to be negatively correlated in the frontal cortex in healthy subjects (Moresco et al. 2002) and in the prefrontal cortex in patients who attempted suicide (van Heeringen et al. 2003). Clinical and epidemiological studies have consistently shown that one or more anxiety disorders occur in the majority of people with AN or BN (Godart et al. 2002; Kaye et al. 2004; Kendler et al. 1995; Walters and Kendler 1995). Silberg and Bulik (2005), using twins, found a unique genetic effect that influences liability to early anxiety and eating disorder symptoms. When a lifetime anxiety disorder is present, the anxiety most commonly occurs first in childhood, preceding the onset of AN or BN (Bulik et al. 1997; Deep et al. 1995; Godart et al. 2000). Anxiety and harm avoidance remain elevated after recovery from AN, AN-BN, and BN (Wagner et al. 2006a), even if individuals never had a lifetime anxiety disorder diagnosis (Kaye et al. 2004). Finally, anxiety (Spielberger et al. 1970) and harm avoidance from Cloninger's Temperament and Character Inventory (Cloninger et al. 1994) have been a robust signal in genetic studies (Bacanu et al. 2005). In summary, the premorbid onset and the persistence of anxiety and harm avoidance symptoms after recovery suggest these are traits that contribute to the pathogenesis of AN and BN. The PET imaging data suggest that such behaviors are related to disturbances of 5-HT and dopamine neurotransmitter function in limbic and executive pathways.

This technology holds the promise of a new era of understanding the complexity of neuronal systems in human behavior. For example, postsynaptic 5-HT$_{1A}$ receptors (Celada et al. 2001; Richer et al. 2002; Sibille et al. 2000; Szabo and Blier 2001) have downstream effects and interactions with other neuronal systems, such as norepinephrine, glutamate, and γ-aminobutyric acid (GABA). Enhanced 5-HT$_{1A}$ activity in AN and BN may cause or reflect an altered balance between these neuronal systems. Moreover, 5-HT$_{1A}$ receptors interact with other 5 HT receptors such as 5-HT$_{2A}$ (Martin et al. 1997;

Szabo and Blier 2001). 5-HT_{1A} postsynaptic receptors mediate locus coeruleus firing through 5-HT transmission at 5-HT_{2A} receptors (Szabo and Blier 2001). Theoretically, increased 5-HT_{1A} and reduced 5-HT_{2A} postsynaptic receptor activity in AN might result in an increase in noradrenergic neuron firing (Szabo and Blier 2001). Moreover, postsynaptic 5-HT_{1A} receptors hyperpolarize and 5-HT_{2A} receptors depolarize layer V pyramidal neurons (Martin-Ruiz et al. 2001). In AN, synergistic effects of these receptors, which are collocated on pyramidal neurons, may reduce pyramidal neuronal excitability.

In summary, these PET–radioligand studies confirm that altered 5-HT neuronal pathway activity persists after recovery from AN and BN and support the possibility that these psychobiological alterations might contribute to traits, such as increased anxiety, that may contribute to a vulnerability to develop an eating disorder.

CONCLUSION

There remain daunting challenges to the investigation of neurobiological mediators of risk and clinical pathology in AN and BN. To what extent abnormalities detected are consequences of pathological eating behavior, malnutrition, or their long-term sequelae remains speculative. Data on the functional status of these neurobiological systems are too sparse to allow for definitive conclusions regarding the possible etiological significance of differences reported between individuals with eating disorders and healthy control subjects.

Clearly, many of the alterations in neuropeptide and monoaminergic function in eating disorders are state dependent; however, given the effects of these systems on mood, anxiety, memory organization, and body physiology, these alterations may well have significant pathogenic influences, both sustaining and exacerbating certain psychological and cognitive elements of these syndromes. Thus, neurobiologically mediated effects may be contributing factors to the frequently long-term, pernicious, and self-sustaining course of illness, at least in many patients. These associations, although speculative, nevertheless underscore the importance of aggressive and sustained treatment of both the nutritional and the behavioral/psychological elements of the syndromes to allow for stabilization and possible normalization of neuropeptidergic and monoaminergic functions.

Still, several lines of evidence from family and twin research, premorbid and retrospective data, and studies with recovered individuals suggest that traits, perhaps related to 5-HT modulation of anxiety and perfectionistic obsessiveness, create a susceptibility for some people to develop an eating disorder. Adolescence is a time of transition, where individuals leave the security of their home environment and must learn to balance immediate and long-terms needs and goals in order to achieve independence. For such individuals, learning to flexibly interact and master complex and mixed cultural and societal messages and pressures, or cope with stress, may be difficult and overwhelming, exacerbating underlying traits of harm avoidance and a desire to perfectly achieve.

To a large extent, current treatments for AN and BN have been based on therapies developed for other psychiatric disorders. While these are effective to some degree, particularly for BN, many individuals with AN and BN remain ill for many years and have only partial resolution of symptoms with treatment. Thus, there is a substantial need to understand how neurobiological risk factors contribute to symptoms, as well as the interaction of temperament with the environment, in order to develop specific and more effective therapy for these disorders.

Chapter 51. Neurobiology of Personality Disorders

NEUROBIOLOGY OF PERSONALITY DISORDERS: INTRODUCTION

The personality disorders as represented in the DSM-IV-TR (American Psychiatric Association 2000) and ICD-10 (World Health Organization 1992) classification systems are characterized by trait-like disturbances in emotion, cognition, and social function. As a group, they share the important commonalities of chronic course with early onset, relative preservation of intelligence, and absence of gross neurological deficit. In order to summarize the neurobiological literature, we have chosen a heuristic organization that emphasizes the location of "lesion" of personality disorder within neural networks mediating mental activity. This is opposed to a model that locates the lesion in *personality,* phenomenology (Siever and Davis 1991), or molecules. All of these are equally valid as heuristics. The advantage of this approach is that it allows a novel, useful reorganization of the existing database, characterized by a close relationship between the identified neurobiological abnormalities and a neurobiologically plausible brain-based model.

We propose that three principal neurobiological processes may be affected lastingly in personality disorder: 1) representation, the working memory process whereby information about the environment is accurately held in biological neural networks; 2) metarepresentation, multidimensional representations of aspects of the self, the environment, and others that permit self-consciousness and social interaction; and 3) motivation and emotion, the process by which discrepancy between an internal motivational state and current state is registered by neurotransmitter- and/or neuropeptide-mediated feedback loops.

This model is clearly not complete, nor is it intended to propose the existence of three biologically discrete categories of personality disorder. Its value is that it facilitates organization of recent findings regarding the neurobiology of personality disorder into a model of mind–brain operations that will remain compatible with rapid advances in the neurosciences in the near future.

WHAT IS A NEUROBIOLOGY OF PERSONALITY DISORDERS?

There is no question that the brain mediates normal and abnormal mental activity. However, it is fair to ask if speaking of a *neurobiology* of personality disorders is a *category mistake,* a mixture of incompatible forms of knowledge. On the one hand, there is general agreement that some aspects of personality disorder (e.g., anxiety proneness, impulsivity) are validly modeled by genetically based, molecularly mediated *traits* that are preserved across cultures (Yamagata et al. 2006). Such traits can be biologically and behaviorally modeled in nonhuman animals. This approach is firmly validated by the remarkable preservation of the molecular building blocks of brain and nervous function throughout evolution and across species, as exemplified by the similarity of amino acid sequences for neurotransmitters, neuropeptides, and associated receptor systems across phylogenies. Alterations of these systems bias behavior and mentation *probabilistically.* This molecularly based, dimensional *trait* perspective has proven to be of value in reducing the complexity of brain and behavioral relationships. However, the dimensional trait perspective does not account for other important features of personality disorder (e.g., suicide, self-injury, social dysfunction) that do not yet have animal model equivalents and to date are most readily studied in human volunteers, using techniques such as behavioral measurements, electrophysiology, functional neuroimaging, and quantitative assay of

biological specimens. It is assumed that these complex phenomena develop over time, with interaction between genes and environment, and involve decision-making processes. It is not yet clear if these represent trait-like dimensions, or if there are clear demarcations between abnormality and normality. As has been pointed out by Kendler (2005), overly strict biological reductionism is an insufficient approach, insofar as the complexity of the molecular determinants is more than matched by the complexity of neuronal networks that have developed in interaction with the environment. However, personality disorders are still clearly biological in the sense that their symptoms are mediated by dysfunction in neuronal networks located in the brain. Definitive progress will eventually depend on our ability to adequately model the biological neural networks and developmental processes that underlie what has traditionally been understood in psychiatry in psychological or *folk psychological* terms.

A heuristic approach to organizing the existing database is justified by the lack of certainty that existing personality disorder categories truly carve "at nature's joints." The most recent behavioral genetic studies confirm the existence of complex genetic relationships *between and within* the Cluster A, B, and C disorders as currently defined (Fogelson et al. 2007; Kendler et al. 2007; Reichborn-Kjennerud et al. 2007; Torgersen et al. 2008). The results are too complex to summarize here, but they simultaneously *confirm some* and *dispute other* cluster, dimensional, and categorical attempts at personality disorder description. An important conclusion of this work is that speaking of the neurobiology of any given specific Axis II disorder is premature without the caveat that the current Axis II nosology contains heterogeneity and overlap. Thus, becoming overly focused on differences and similarities between disorders (e.g., antisocial vs. borderline personality disorder) could result in conclusions that are invalid due to invalid premises.

REPRESENTATION

The process whereby information regarding the environment is represented in symbolic form by electrophysiological activity in biological neural networks is known as *representation.* Abnormalities in representation are the prominent feature of schizotypal personality disorder, but stress may cause transient abnormal representation in the Cluster B disorders as well.

Representation is mediated by reverberant neural activity (i.e., oscillations) over widely distributed and highly interconnected networks of pyramidal cells and associated neurons. Persistence of activity in networked circuits of corticothalamic and cortico-cortico neurons can sustain a neural representation even after the original stimulus is no longer present. If the representation concerns an environmental stimulus, the corresponding areas of primary and secondary sensory cortex mediate representation of sensory information, but other brain regions are also activated in the process. For example, verbal working memory tasks are associated with activation of parietal and cerebellar brain regions, in addition to prefrontal and temporal regions (Paulesu et al. 1993). To what extent neural resources are utilized for the representation of a stimulus is partially determined by the salience of the stimulus. The *anticipated* reward value of a stimulus is reflected in the gain of delay activity (persistent activity) of the dorsolateral prefrontal cortex (Postle 2006; Sawaguchi and Yamane 1999), although not all information processed in the brain necessarily passes through circuits in the dorsolateral prefrontal cortex. Thus, working memory processes are shaped by the interaction of attention and representation (Fuster 2006).

It is useful here to review the biological building blocks of working memory before moving on to abnormalities associated with personality disorder. Synchronization of network oscillations is regulated by fast-spiking γ-aminobutyric acid (GABA) neurons, which are in turn modulated by glutamate inputs. Network oscillations facilitate information transfer across different brain regions, and according to the *global workspace theory,* their synchronization is important for the binding of disparate aspects of a stimulus in conscious awareness. According to the Cohen-Braver-Brown hypothesis (Cohen et al. 2002), dopamine plays a key role in modulating the activity of oscillating

cortical circuits. An optimal balance of tonic (D_1) and phasic (D_2) dopaminergic tone shapes the signal-to-noise characteristics of information flow in the prefrontal cortical neural networks. Tonic D_1 receptor stimulation stabilizes neural network activity around attractors. Phasic "bursts" of D_2 receptor stimulation in the striatum reset prefrontal cortical neural networks and open a subcortical, striatal "gate" for salient information. D_1 and D_2 functions are interrelated, with D_1 tone restraining D_2 activity. The end result of low D_1 tone according to the computation model is reduced signal-to-noise ratio, instability of neural network state, and aberrant assignment of salience to information. This may be apparent to an outside observer as increased distractibility and unreliable or invalid salience being attributed to stimuli. It may also be measured by an observer as eye-tracking abnormalities. The reason for this is that tracking of a moving object in space with the eyes requires working memory "buffers" to constantly update and store visual information and eye movement position.

Abnormalities in the Neurobiology of Representation in Schizotypal Personality Disorder

It is of great interest then that schizotypal personality disorder has been associated with eye-tracking abnormalities (Siever et al. 1991) and that eye-tracking abnormalities are correlated with the dimensional severity of psychotic-like and schizotypal-like characteristics (Siever et al. 1984). Confirmation of connections between eye-tracking abnormalities and schizotypy comes from follow-up studies of visual and auditory attention/working memory (Condray and Steinhauer 1992; Harvey et al. 1996; Lees Roitman et al. 1997; Siever 1985). Neurophysiological studies have found disturbed neural network function during working memory tasks in schizotypal personality disorder, in the form of diminished slow negative potential magnitude (or contingent negative variation) (Klein et al. 1999). Additionally, electroencephalographic activity in the theta-band, believed to correspond to memory-related representational processes and originating from the hippocampal generators, has been found to be decreased in patients with schizotypal personality disorder versus controls (Lazarev 1998).

As dopamine receptor blockade is essential for antipsychotic drug efficacy, dopamine is a candidate neurotransmitter mediator of psychosis and working memory breakdown. Homovanillic acid (HVA), the product of dopamine metabolism, is measurable in the cerebrospinal fluid (CSF) and may serve as an index of brain dopamine activity. CSF HVA levels are positively related to severity of psychotic-like symptoms in schizotypal personality disorder (Siever et al. 1991), as has been found in schizophrenia (Pickar et al. 1990). Elevated brain HVA concentration may reflect diminished D_1 receptor activity; D_1 receptors are more widely expressed in the brain relative to D_2 or other dopamine receptors, and administration of D_1 receptor antagonists is associated with increased local HVA concentration (See et al. 1991). As dopamine receptors are most densely expressed in the striatum, dysfunction in this brain region may be related to dopaminergic problems. Lower left and right caudate nucleus volumes have been found in schizotypal personality disorder subjects compared with normal control subjects (Levitt et al. 2002). Consistent with this, schizotypal personality disorder patients exhibit lower resting regional glucose metabolism in the caudate, as compared with patients with schizophrenia or normal control subjects (Shihabuddin et al. 2001). Structural and functional regional findings in the putamen mirror those of the caudate, with schizotypal personality disorder associated with decreased putamen size (Shihabuddin et al. 2001) and resting metabolism (Buchsbaum et al. 1992), although increased putamen resting glucose metabolism is also reported (Shihabuddin et al. 2001). In general, these findings are consistent with underlying abnormalities in striatal structure and function, and they support the plausibility of a dopamine-related functional deficit in striatal gating of information in schizotypal personality disorder.

It would be premature to conclude that there is a localized striatal or frontal "lesion" underlying schizotypal personality disorder, however. The neural circuits implicated in working memory deficits in schizotypal personality disorder are widely distributed across the brain and include the frontal,

temporal, and parietal cortex (Koenigsberg et al. 2005). Additionally, brain structural differences between schizotypal personality disorder subjects and controls implicate a wider circuit that includes the temporal lobes and thalamus (Dickey et al. 2002). In summary, a significant body of work describes abnormal function and structure of widely distributed neural circuits involved in working memory and representational processes. Dopamine plays a key role in these processes, and indices of abnormal dopamine function have been associated with schizotypal personality disorder. Other biological factors such as GABA and glutamate are also likely to play a role in dysfunctional representational processes in schizotypal personality disorder but have not yet been extensively studied.

Genetics of Cluster A Personality Disorders

Schizotypal personality disorder is more prevalent among first-degree relatives of persons with schizophrenia. This relationship to schizophrenia seems to be specific to schizotypal personality disorder, as it is present only in diminished form with paranoid, schizoid, and avoidant personality disorder and is absent with borderline personality disorder (BPD) (Fogelson et al. 2007; Kendler et al. 1993). It is thought that the trait of schizotypy is conserved because of the increase in fitness that accompanies some aspects of it, such as creative nonconformity (Nettle 2006) on the behavioral level or neural network complexity on the molecular level (Burns 2004). High heritability (72%) has been found for dimensional measures for schizotypy. Molecular genetics studies confirm shared susceptibility between schizotypal personality disorder and schizophrenia (Fanous et al. 2007). Schizotypy has been associated with a high-activity catechol-*O*-methyltransferase (COMT) genotype in a single study (Schurhoff et al. 2007), as well as a functional polymorphism of the neuroregulin-1 (*NG1*) gene (Lin et al. 2005). However, the field is still quite far from understanding the molecular determinants of schizotypy.

METAREPRESENTATION

Disturbed self-concept, empathy, social attribution, and social interaction are critical aspects of personality disorder that are mediated in brain neuron networks by metarepresentation (sometimes referred to as metacognition). Metarepresentation refers to the symbolic representation of the self in the context of its environment. The environment is not merely the physical environment but could include "meta" spaces such as a social environment. Metarepresentational abnormalities include visuospatial processing deficits (BPD), aberrant social cognition (in nearly all personality disorders), and deficiencies in self-awareness (alexithymia, poor self-concept, and inaccurate sense of social worth, primarily in borderline, narcissistic, histrionic, dependent, and avoidant personality disorder).

In addition to the working memory processes of the prefrontal cortex, metarepresentation additionally relies on analog and digital-like computational processes native to the parietal cortex (Tudusciuc and Nieder 2007). Neural networks in these regions are specialized in multimodal sensory and object processing and visuospatial processing, as well as the processing of symbolic objects (i.e., mathematics and language). Importantly, representation of the position of the self in physical space is dependent on intact parietal function, as lesions here result in the rapid decay of the sense of one's own body position. Movement-related proprioceptive information can refresh the sense of the body in space, but the information rapidly decays until movement occurs again (Arzy et al. 2006a).

All available evidence points toward overlapping neural circuits involved in the processing of the body in physical space and in "social" space. So-called mirror neurons in the parietal lobe respond automatically to the body movements of the self *and* others and reflect the importance of the parietal lobe in social communication, as well as the automatic parallel structure of social cognitive processing. It is not yet clear to what degree these processes are automatic or require effortful attention (reviewed in Satpute and Lieberman 2006). Preliminary findings suggest that at least some portion of metarepresentational processes that mediate social cognition is automatic. Examples include

temporoparietal alpha-band electroencephalographic activity evoked during human social interaction and parietal neuron spiking in socializing nonhuman primates (Fujii et al. 2007). Effortful social cognition, such as empathy or accurate attribution, is likewise associated with the activity of the parietal cortex (Fogassi et al. 2005), although prefrontal regions may be necessary for processing of emotion-related information (Saxe 2006). Self-consciousness is another form of metarepresentation that similarly relies on distributed networks that include the frontal, temporal, and parietal brain regions. Intact function of the parietal precuneus may be a *necessary* condition for self-consciousness, as deactivation of the precuneus with anesthetic agents is characterized specifically by a temporary loss of high-order representation of body or self (Cavanna and Trimble 2006; Maquet et al. 1999). Dissociative episodes can be marked by disturbed awareness of one's own body. It is of interest then that stimulation of the temporoparietal junction results in out-of-body experiences similar to those experienced during intense episodes of depersonalization (Arzy et al. 2006b).

Cholinergic neurons from the substantia inominata/nucleus basalis magnocellularis enervate the frontal and parietal cortex. Disruption of the cholinergic neurons of the parietal cortex is associated with impaired attention and learning, in the absence of deficits in classical conditioning, suggesting a role for these parietal neurons in effortful learning (Thiel et al. 2005). Serotonin (5-HT) is also important in the development and function of the parietal cortex. During in utero and infant development, serotonin is a powerful signal for cortical development. Disrupted 5-HT metabolism results in the poorly differentiated laminar cortical barrels (Osterheld-Haas and Hornung 1996), with severe deficits in the development of sensory and cognitive capacities related to the type of cortex affected. Less dramatic variations in 5-HT metabolism, in the form of genetic polymorphisms of the 5-HT transporter and/or monoamine oxidase A enzyme, probably exert their greatest effect during neural development. In adulthood, 5-HT alters signal-to-noise characteristics of pyramidal cell networks, and administration of fluoxetine grossly increases the metabolic rate of the parietal cortex (Buchsbaum et al. 1997).

It is established that metarepresentational capacities are shaped by gene–environment interaction. Biologically informed neural network models confirm the importance of parietal and frontal lobe interactions in shaping development (Edin et al. 2007). The development of visuospatial working memory ability in humans over the first two decades of life is paralleled by age-related changes in frontoparietal network activations during visuospatial working memory performance (Kwon et al. 2002); the protracted time course of this development suggests that the process is complex. Accordingly, connectivity between frontal and parietal lobes has been shown to increase in early childhood and continue to increase through adolescence, as measured by diffusion tensor imaging (DTI) (Olesen et al. 2003). It is biologically plausible that disruptions in normative processes such as abnormal parental care or exposure to environmental toxins could derail optimal development. As an example, in animals early-life environment has been demonstrated to affect the expression of parietal serotonin$_{2A}$ (5-HT$_{2A}$) receptor mRNA (Vazquez et al. 2000).

Parietal Lobe Dysfunction in Borderline Personality Disorder

Patients with BPD have difficulties with visual memory and visuospatial abilities in the absence of gross deficits of executive function (Beblo et al. 2006b). This raises the possibility that in addition to frontolimbic connectivity (see below), BPD may be associated with abnormal frontoparietal connectivity. Electrophysiological evidence corroborating deficits in frontoparietal connectivity includes findings of decreased P300 amplitude to novel stimuli in a multitude of event-related potential (ERP) studies (reviewed in Boutros et al. 2003) and decreased gamma frequency range neural synchrony of posterior cortical regions during early phases of stimulus processing (Williams et al. 2006). Criminal psychopaths have also been found to have decreased amplitude of late (>300 msec) positivity over parietal electrodes to novel stimuli (Howard and McCullagh 2007), suggesting

that this abnormal parietal neural synchronization may underlie the known overlap between borderline and antisocial personality disorder.

In addition to the electrophysiological abnormalities, BPD has been consistently linked to structural and functional parietal findings. Patients with BPD compared with matched controls have smaller parietal lobe volume (Irle et al. 2005) and diminished resting parietal metabolic rate (Lange et al. 2005; Lepping and Swinton 2004). During tasks designed to stress cortical circuits, BPD patients show exaggerated parietal metabolism (Beblo et al. 2006a; Schnell et al. 2007). This is interpretable as a compensatory mechanism for decreased processing efficiency. Parietal serotonergic function may be impaired as well, as there is evidence of decreased parietal metabolic activation following pharmacochallenge with the 5-HT releasing agent fenfluramine in BPD (Soloff et al. 2000).

Disturbances in Awareness

Dissociation is perhaps the most dramatic disturbance of metarepresentation, in which the experience of the self is disturbed. Dissociation usually occurs during a stressful experience and is most closely associated with BPD. Although dissociation is usually associated with psychopathology, it can also be evoked in healthy individuals, although without the same level of severity. Evidence suggests that the tendency to dissociate is heritable (Jang et al. 1998) and is associated with emotion dysregulation and suspiciousness (de Ruiter et al. 2007). Thus, its neurobiology should be tractable to investigation.

States of stress and high arousal are characterized by glutamatergic, dopaminergic, and noradrenergic hyperactivity that may impair prefrontal cortical information-processing ability. Dopamine and norepinephrine function are thought to exhibit an inverted U-shaped relationship with prefrontal cortical information-processing capacity. It has been hypothesized that dissociation permits learning during an otherwise overwhelmed, dysfunctional state (de Ruiter et al. 2007), or it may serve to decrease arousal by modulating neural function in the prefrontal, limbic, and parietal brain regions, in much the same way that hypnosis decreases pain perception by modulating brain function (Roder et al. 2007). On the other hand, dissociation does not always occur in reaction to stress. In depersonalization disorder, individuals may feel dissociated in the absence of stress, and during these episodes, metabolism is increased in the right parietal lobe (Simeon et al. 2000).

Individuals with depersonalization disorder, like patients with BPD, also show deficits in visuospatial information processing, with deficits in visual working memory and spatial reasoning. Therefore, individuals prone to dissociation may have an underlying parietal cortex vulnerability or faulty connectivity with the parietal cortex. This vulnerability could manifest itself at baseline with subtle difficulties in visual working memory; under stress, the vulnerability may be unmasked in a breakdown in metarepresentation of the self or even in representation of the environment. We do not yet know whether the underlying biological abnormalities also affect self-awareness in social cognition (e.g., representation of one's own social value). However, a lack of awareness of one's actual social worth is manifested in narcissistic and antisocial personality disorder as overestimation of one's self-worth and contempt for others. In BPD and histrionic personality disorder, it is manifested by contempt for the self and dependency on others. Very little attention has been paid to why these seemingly opposite tendencies occur in genetically related disorders and whether this phenomenon represents a sexually dimorphic expression of a common neurobiological problem.

Perfectionism

Perfectionism is a psychological tendency to hold the self or others to an unnatural standard with respect to performance, beauty, or other attributes. It is most closely associated with obsessive-compulsive personality disorder (OCPD) (Halmi et al. 2005), especially when OCPD is comorbid with an eating disorder or obsessive-compulsive disorder (OCD) (Coles et al. 2008). Abnormal dopaminergic function is implicated in perfectionism. OCPD has been associated with polymorphisms of the dopamine D_3 receptor gene (Light et al. 2006). The association is plausible, as stimulation of

the striatal D_3 receptors can cause compulsive, repetitive behavior. The severity of perfectionist traits in eating disorders has been associated with DRD4 polymorphisms (Bachner-Melman et al. 2007). Dopaminergic abnormalities would be expected to heighten approach/avoidance conflicts that occur during evaluation of self or others. Such a process in theory would result in behavioral manifestations of perfectionism. 5-HT dysfunction may also play a role. By inhibiting reversal learning, serotonergic deficits may contribute to the narrow focus on seemingly arbitrary or inappropriate goals (Clarke et al. 2007). Further work is necessary to explore specific relationships between serotonergic function and perfectionism in OCPD.

MOTIVATION AND EMOTION

Disturbances in brain-based motivational and emotion systems result in some of the most self-destructive symptoms of personality disorder, such as suicidality, self-injury, violence, and reckless behavior. Psychological conceptualizations of emotion have tended to emphasize the subjective experience of affect and how this is mediated by brain activity. Although useful, this emphasis runs the danger of placing a hidden observer in an infinitely receding phrenological conception of brain function and when overemphasized results in a conceptual and clinical dead end. Neural network models of brain function focus on the more tractable issue of *feedback systems for control.* Hence, E. T. Rolls (2000) defined emotion is an internal motivational state transiently evoked by positive or negative reinforcers. The experience of affect provides motivation for motor behavior, whether it is appropriate and/or adaptive or not. So-called *primary reinforcers* include stimuli with intrinsic negative or positive survival significance (e.g., the pleasant taste of palatable food). So-called *secondary reinforcers* are more complex, involving multidimensional representations (e.g., a context of perceived social threat). Thus, emotional processes involve the modification of representations of the reinforcement value of an attended stimulus (e.g., the appetitive aspects of the odor of food) by a continuously updated representation, or metarepresentation, of motivational state (e.g., nutritional need). Thus, both emotion and motivation are slightly different aspects of a complex system that has evolved to guide decision making and behavior.

Circuits that traverse, among other brain regions, the amygdala and orbitofrontal cortex are necessary to be able to update the reinforcement value of a stimulus held in working memory with new information. Circuits including the medial prefrontal cortex, orbitofrontal cortex, insula, amygdala, bed nucleus of the stria terminalis, parietal lobes, and cerebellum are involved in the maintenance of internal motivational states and affect. Induction of such subjective states can predictably bias the interpretation of internal and external stimuli and thus have a strong but *probabilistic* effect on motor response. Abstract representations of motivational state are mediated by hypothalamic and brain stem networks. Within these structures, neuropeptides such as corticotropin-releasing hormone (CRH), vasopressin, and oxytocin play important signaling roles. Disruption of normal neuropeptide signaling results in abnormal development and severe dysregulation of motivated behaviors such as feeding, sex, and attachment. Neuropeptide signaling appears to play a *deterministic* role on behavior. Sometimes, but not necessarily always, these modifications can be accompanied by the induction of a subjective state (e.g., hunger). Finally, working memory and metarepresentation are both implicated in emotion in motivation, as these processes require reinforcement information to be sustained and processed.

All three of the monoamine neurotransmitters (serotonin, norepinephrine, and dopamine) have receptors in frontal cortical and limbic brain regions. Stimulation of monoamine receptors with a change in synaptic monoamine neurotransmitter level alters the input gain and output gain of information-processing circuits of predominantly pyramidal cell neurons in the cortex. This permits systematic and coordinated adjustment of the signal-to-noise properties of neuronal networks in the cortex. The resulting change in information processing can thus have effects on emotion and motivation. When monoamines are altered by a drug or medication, an artificial state is induced. It is

important to remember that usually the brain stem nuclei coordinate changes in monoamine neurotransmitter drive in concert with changes in internal motivational state. Stimulation of monoamine receptors in brain regions such as the hypothalamus can also alter neuropeptide release, and neuropeptides can have more direct effects on emotion and motivation. Finally, monoamine receptor stimulation of brain stem structures may stimulate autoreceptors, which may have global effects on monoamine function. Thus, it is not surprising that altering any one of the three monoamines with psychotropic drugs can reliably alter emotional state. Dopamine powerfully affects the striatum and can thus directly the hedonic quality of stimuli and can quickly affect the motor response to motivational states. Norepinephrine powerfully stimulates the amygdala, prefrontal cortex, and hypothalamus and thus can cause arousal. Even in phylogenetically distant animals such as the mollusk, 5-HT release is involved in the regulation of approach and avoidance behaviors (Inoue et al. 2004). 5-HT is complex in its actions, with phasic-like serotonergic function being implicated in states of high arousal and heightened emotionality and tonic-like serotonergic function being implicated in the regulation of other biological systems such as the hypothalamic-pituitary-adrenal (HPA) axis and dopaminergic function in the striatum and cortex. Additionally, modulation of 5-HT by proserotonergic drugs is known to facilitate reward processing (Vollm et al. 2006).

Nonmonoamine neurotransmitters are also implicated in the neurobiology of abnormal emotion in personality disorder. These include the excitatory neurotransmitters (glutamate), inhibitory neurotransmitters (GABA), and the neuropeptides (vasopressin, oxytocin, cholecystokinin, CRH, thyroid hormone).

We have selected four common symptoms of personality disorder that reflect disrupted emotion/motivation systems: 1) impulsivity, 2) aggression, 3) affective instability, and 4) suicide. It is clear that the underlying neurobiology of these "symptoms" overlap, and so it is not surprising that when one is present, the chance of finding others is high.

Impulsivity, Serotonin, and the Orbitofrontal Cortex

Although the term *impulsivity* is sometimes casually employed to describe recklessness, a more careful accounting provides better insight into the underlying process of impulsivity. The ability to delay gratification (or tolerate frustration) relies on delay discounting, mediated by the so-called delay neurons of the orbitofrontal cortex. These neurons encode the time-decay function of the reinforcement value of a stimulus. In general, future rewards are devalued relative to immediate rewards. The steepness of the time-decay function may be modulated by intense motivational states, and thus the steepness probabilistically affects a motor response. Consistent with an underlying orbitofrontal cortex–based defect in the representation of time-delayed reinforcement value, patients with BPD exhibit an abnormal sense of elapsed time (Berlin and Rolls 2004) that is actually more accelerated even than in patients with orbitofrontal cortex lesions. Patients with antisocial personality disorder also show acceleration of time estimation, and this deficit is accompanied by either higher amplitude or faster rise time of the Contingent Negative Variation, a slow (>300 msec) negatively sloped change in cortical electrical field potential over the frontal cortex (Bauer 2001). It is possible that this behavioral abnormality is related to abnormal ventral prefrontal structural connectivity (Rüsch et al. 2007), functional connectivity (New et al. 2007), or function (Soloff et al. 2003).

Impulsivity related to intolerance of frustration can be conceptualized as a manifestation of so-called frustrative nonreward, the phenomenon of increased arousal and appetitive behavior in response to surprising or inconsistent reinforcement. Frustrative nonreward is an aversive state. It is associated with hypothalamic-pituitary activation (Lyons et al. 2000), as well as noradrenergic activation. Indeed, severity of impulsivity is correlated with sensitivity to frustrative nonreward (Douglas and Parry 1994). As frustrative nonreward involves the neural circuits controlling appetitive behavior, it is abolished by depletion of dopamine, which is released in response to reward availability (Taghzouti et al. 1985). Trait impulsivity is also linked to dopamine, as individuals with higher trait impulsivity show

greater sensitization of dopamine release in the ventral striatum, dorsal caudate nucleus, and putamen, as measured by [^{11}C]raclopride binding (Boileau et al. 2006). Additionally, genetic polymorphisms of *COMT* and *DRD2* (the gene encoding the D_4 dopamine receptor) predict impulsivity-related personality traits (Reuter et al. 2006). Impulsive reward-sensitive individuals are more likely to experience frustrative nonreward (Corr 2002). 5-HT has been demonstrated to have a constraining effect on impulsivity. It is possible that personality disorder patients high in impulsivity may thus have deficiencies in serotonergic modulation of the aversive aspects of frustrative nonreward and consequently have greater difficulty suppressing appetitive behaviors even when they are harmful. Impulsive BPD patients have higher availability of the 5-HT transporter in the hypothalamus and brain stem, as measured by [I^{123}]ADAM (2-([2-([dimethylamino]methyl)phenyl]thio), a 5-HT transporter–specific radioactive ligand (Koch et al. 2007). They may also have lower 5-HT synthesis capacity in the medial prefrontal gyrus, anterior cingulate gyrus, temporal gyrus, and striatum, as evidenced by a brain PET imaging using the tryptophan precursor tracer α-[^{11}C] methyl-L-tryptophan (α-[^{11}C]MTrp) (Leyton et al. 2001). Increased 5-HT transporter availability *and* decreased 5-HT synthesis could result in a relative hyposerotonergic state, which in turn could decrease frustration tolerance or increase frustrative nonreward, thereby contributing to impulsivity.

While impulsivity in BPD is linked to emotion dysregulation, some manifestations of impulsivity may be linked to emotional underarousal and insensitivity to negative reinforcement. In *psychopathic* individuals with antisocial personality disorder, impulsivity has been linked to decreased trait anxiety (Fowles 2000) and decreased skin conductance (sympathetic underarousal). These deficits most likely reflect inadequate or abnormal reactivity of limbic and prefrontal neuronal networks. This has been demonstrated as decreased blood oxygen level–dependent (BOLD) signal response in limbic and prefrontal networks following exposure to arousing and aversive stimuli (Birbaumer et al. 2005). In contrast to impulsivity, deceitful aspects of psychopathy may be related to increased, rather than decreased, serotonergic function, as measured by prolactin response to fenfluramine (Dolan and Anderson 2003). These findings would predict that augmenting serotonergic function with medications would not be expected to alter deceitful aspects of psychopathy. On the other hand, knowledge of subsensitivity to punishment and anxiety, and relative hypersensitivity to reward, may be utilized in the treatment of individuals with substance abuse disorders, many of whom exhibit psychopathic traits (Messina et al. 2003).

Aggression

Aggression encountered in personality disorder is typically classified as impulsive versus nonimpulsive. There is little evidence of a biological distinction between the two subtypes, but the most systematic work has focused on so-called impulsive, reactive, or affective aggression. Impulsive aggression in personality disorder is typically encountered in patients with Cluster A or B disorders. Impulsive aggressive episodes do not typically result in homicide but may result in injury, property damage, or reputation damage. By definition, they cause dysfunction in social relationships. Triggers for acts of impulsive aggression are usually either agonistic social interactions or frustration. Neuropeptides such as CRH, vasopressin, and oxytocin play an important role as mediators of change in social motivational state. Monoamines, as reviewed above, are important in mediating emotional reactivity (anger, contempt) and in processes related to impulsivity (frustrative nonreward). Thus, impulsive aggression represents a complex phenomenon, concatenating social behavior, emotion, and impulsivity.

A considerable amount of research has focused on the finding of low 5-HT metabolite levels in abnormal aggression. A simple correlation between 5-HT "level" and aggression is probably invalid, given the complexity of 5-HT's role in a wide range of neural functions. 5-HT levels in the brain are at their lowest during rapid eye movement sleep, but are acutely and phasically released in the brain during agonistic social encounters between conspecifics. Interestingly, prefrontal cortical levels of

5-HT and 5-hydroxyindoleacetic acid (5-HIAA) *decrease* preceding an aggressive attack (van Erp and Miczek 2000), suggesting that regardless of what happens after an aggressive encounter, low prefrontal 5-HT remains a risk factor for aggressive behavior. In total, these data suggest that low 5-HT in prefrontal cortical circuits may prime an aggressive response, while elevated 5-HT levels during agonistic encounters reflect 5-HT released during motor activity. Early human studies found reduced levels of CSF 5-HIAA to be associated with aggression and suicidal behavior (Brown et al. 1979) and impulsive homicide (Linnoila et al. 1983), although not all studies to date have found an inverse relationship between CSF 5-HIAA and aggression (Balaban et al. 1996). CSF 5-HIAA provides an incomplete picture of serotonergic function, and thus other indices have been examined. Fenfluramine, which is an agonist at the 5-HT_{2A} and/or 5-HT_{2C} receptor site, has been used extensively to study postsynaptic 5-HT receptor function by measuring the pituitary prolactin response to fenfluramine challenge (Coccaro et al. 1996; Park and Cowen 1995). Coccaro et al. (1989) found that aggression was correlated with decreased prolactin response to fenfluramine in personality disorder subjects. The correlation of decreased responsiveness of the serotonergic system with impulsive aggression has been replicated in personality disorder subjects (Stein et al. 1996), in antisocial violent offenders (O'Keane et al. 1992), and in primates (Botchin et al. 1993) and remains one of the most replicated findings in biological and clinical psychiatric research.

A separate strand of research has focused on the role of the prefrontal cortex in impulsive aggression. Aggressive personality disorder individuals have reduced resting state metabolism in the orbitofrontal cortex and right temporal lobe (Goyer et al. 1994). These metabolic abnormalities may be related to an underlying structural abnormality in neural circuits residing in prefrontal cortical gray matter, which is reduced in volume in aggressive antisocial personality disorder individuals (Raine et al. 2000). Impulsive aggressive individuals have exaggerated amygdala blood flow *increases* and orbitofrontal blood flow *decreases* in response to passive viewing of angry facial expressions (Coccaro et al. 2007). As impulsive aggression has previously been associated with difficulty in correctly identifying angry and disgusted facial expressions (Best et al. 2002), this suggests that the increased amygdala blood flow response measured by functional magnetic resonance imaging (fMRI) during viewing of angry faces may reflect inefficiency in neural network processing, in line with resting state and structural study findings. Findings of disturbed structure of inferior frontal white tracts in impulsive, hostile BPD (with comorbid attention-deficit/hyperactivity disorder [ADHD]) patients provide confirmatory evidence of abnormal prefrontal cortex neuronal network architecture as a biological risk factor (Rüsch et al. 2007).

Uniting findings of the serotonergic deficits with prefrontal cortex deficits, several studies now have found serotonergic abnormalities on the brain regional level. Administration of 5-HT receptor agonists in impulsive aggressive individuals results in blunted metabolic activations in orbitofrontal, ventromedial, parietal, and cingulate cortex (New et al. 2002; Siever et al. 1999; Soloff et al. 2000). Putting these findings together, the following interpretations are plausible. The first possibility is that 5-HT receptor subsensitivity in the prefrontal cortex may reflect decreased dynamic range of 5-HT-related neuronal function, and this in turn contributes to aggressive behavior. The second possibility is that aggressive behavior, or other high arousal states, results in compensatory blunting of postsynaptic serotonergic function. Arguing for the validity of the first interpretation and a causal role for serotonergic dysfunction in aggression is the finding that treatment with selective serotonin reuptake inhibitor (SSRI) drugs such as fluoxetine has been shown to *decrease* aggression in personality disorder patients (Coccaro et al. 1997). Additionally, treatment with fluoxetine is associated with increased resting orbitofrontal cortical metabolism, as measured by positron emission tomography (PET) imaging (New et al. 2004), with some evidence of greater efficacy in patients who carry the L allele versus the less potent S allele of the 5-HT transporter (Silva et al. 2007).

Animal studies have clearly implicated vasopressin as a neuropeptide mediator of aggressive behavior (Ferris et al. 1994). Coccaro et al. (1998) found that resting CSF vasopressin level correlated directly

with life history measures of aggression in personality disordered subjects, whereas CSF oxytocin correlates inversely (unpublished data). Although in rodents vasopressin has been demonstrated to directly affect aggressive behavior, it also affects nonaggressive social behaviors such as flank marking. Thus, vasopressin appears to modulate social motivation, above and beyond its effects on aggressive behavior.

Social motivation shares with emotion the representation of an internal motivational state (affiliation and/or dominance) and is highly conserved in vertebrates. The ability to use visual information regarding spatial position as feedback regarding social dominance is confirmed even in fish (Grosenick et al. 2007). Metarepresentation of the social environment may rely on circuits that originally served in the metarepresentation of spatial self–other relationships. As an example, the spatial position of an individual bird in a flock can powerfully predict feeding success and protection from predators (Krause 1994). Finally, the internal motivational state may itself be shifted by hormonal factors into new configurations, such as the effect of testosterone on dominance (Gould and Ziegler 2007) or menstrual cycle–related changes on sexual desire. Incentive-driven social behavior probably relies on the same limbic neurocircuitry that guides other incentive-driven behaviors, as is illustrated by the effect of amygdala lesions on dominance status (Bauman et al. 2006). Further work needs to be done in order to better understand how changes in social motivational state may alter impulsive aggression.

Affective Instability, Frontolimbic Brain Function, and Acetylcholine

In BPD, affective instability is manifest as excessive mood lability and stress reactivity. In histrionic personality disorder, it is manifest as shallow, shifting affect. In comparison with affective disorder patients, affective instability in BPD patients shows more circadian variability and a more random distribution of mood changes (Cowdry et al. 1991) rather than fluctuations between depressive and elated affects (Larsen and Diener 1985).

Psychophysiological data help to confirm that at least some portion of the affective instability of BPD represents excessive reactivity to stressful stimuli, and not simply a reporting bias or willful social manipulation. In response to startling noise bursts, individuals with BPD exhibit an enhanced startle reflex (Ebner-Priemer et al. 2005). Additionally, the induction of an aroused negative mood state potentiates startle magnitude to a greater degree in BPD patients versus controls (Hazlett et al. 2007). Given that the brain stem and spinal cord basis of the startle reflex is subject to top-down modulation by prefrontal and limbic circuits, these findings are suggestive of disinhibition of the startle reflex by either limbic hyperreactivity or deficient prefrontal cortical control.

Neuroimaging studies have focused on abnormalities of the limbic system. BPD has been associated with decreased left amygdala volume (Driessen et al. 2000; Tebartz van Elst et al. 2007), as well as decreased hippocampal volume (Brambilla et al. 2004). Decreased hippocampal volume has also been associated with history of childhood trauma (Vythilingam et al. 2002) and dissociative identity disorder with posttraumatic stress disorder (Vermetten et al. 2006), raising the possibility that exposure to traumatic stress may cause or magnify a structural brain defect. Given the high rates of abuse and neglect in the childhood history of many patients with Cluster B disorders, this is an important question for future research. Although the amygdala may be smaller than normal in some BPD patients, it appears to be *functionally hyperreactive* during tasks of emotion processing (Minzenberg et al. 2007), especially in response to emotionally ambiguous contexts (Schnell et al. 2007). Because of the importance of reciprocal connections between frontal and limbic brain regions in control and communication, structural and functional connectivity has been investigated in BPD. DTI of white matter microstructure has revealed aberrant white matter tracts in the inferior prefrontal cortex in patients diagnosed with comorbid BPD and ADHD (Rüsch et al. 2007), suggestive of connectivity abnormalities within prefrontal circuits, between prefrontal and limbic circuits, or between thalamus and prefrontal cortex. A major shortcoming of this work is its lack of clinical

applicability (as of yet) and its nonspecificity with regard to personality disorder versus affective or anxiety disorder.

Cholinergic neuronal activity in limbic neural circuits is important for information processing and plasticity. Administration of anticholinergic drugs interferes with emotion-related memory processes (Kamboj and Curran 2006a). Anticholinergic drugs have also been found to selectively impair the recognition of anger and disgust (Kamboj and Curran 2006b). Challenge with cholinergic agents causes limbic activation, which can be detected by changes in limbic blood flow and corresponding induction of mood states of fear and euphoria (Ketter et al. 1997). Following challenge with physostigmine, a procholinergic drug, patients with BPD show more severe depressive mood changes compared with other personality disorder patients. Furthermore, the severity of the depressive response was greater in patients with prominent affective instability (Steinberg et al. 1997).

5-HT plays in an important role in cortical information processing and also in constraining the intensity of limbic and hypothalamic stress reactivity. BPD has been associated with 5-HT-related genetic polymorphisms, including the S allele of the 5-HT transporter (Steiger et al. 2005), and polymorphisms encoding high activity of the monoamine oxidase (MAO) gene (Ni et al. 2007). Serotonergic abnormalities have been linked to affective symptoms. 5-HT_{2A} receptor binding is greater in BPD patients with a history of depression, suggesting a role for the 5-HT_{2A} receptor in at least depressive mood changes (Soloff et al. 2007). Patients with histrionic personality disorder, who exhibit rapidly shifting affects, have increased loudness dependence of auditory evoked potentials (AEPs), which is inversely related to serotonergic tone in the cortex (Wang et al. 2006). Further work needs to be done regarding the uniqueness of association of 5-HT-related genetic polymorphisms with personality disorder versus other disorders.

Studies of the hypothalamic-pituitary axis in BPD have found inconsistent results. Data from studies of the dexamethasone suppression test (Beeber et al. 1984; Sternbach et al. 1983) and the thyrotropin-releasing hormone (TRH) stimulation test (Kavoussi et al. 1993) have been inconclusive. These results highlight the biological heterogeneity of the existing categorical groups and suggest that BPD is not as closely associated with HPA axis abnormalities as is affective disorder. On the other hand, central CSF CRH levels are positively related to the severity of early-life parental abuse and neglect in personality disorder (Lee et al. 2005, 2006). This could be of considerable importance, given the inordinately high rates of history of abuse and/or neglect across personality disorder diagnoses. Additionally, it is consistent with preclinical investigation findings that central CRH drive is lastingly affected by early-life disruption of parental care (Coplan et al. 1996; Plotsky and Meaney 1993) and with evidence of peripheral downregulation of pituitary sensitivity to exogenous CRH from our laboratory (unpublished data) and other laboratories in non–personality disorder populations (Heim et al. 1998). What is the consequence of increased central CRH drive as a result of early-life trauma on the brain and behavior? Given the known effect of administering exogenous CRH on inhibiting socialization in primates (Strome et al. 2002), we would postulate that increased CRH drive would induce a form of social anhedonia, which is partially supported by our finding of an association of paranoid personality disorder with elevated CSF CRH (Lee et al. 2006). Although CRH plays a physiological role in normal behavior that provides phenotypic plasticity during times of stress, decreased dynamic range of CRH systems would render the system inflexible to the environment. This work would suggest that CRH receptor antagonists could be of value in the treatment of paranoid anxiety, as is found in paranoid personality disorder. In summary, it seems that dysregulation of the HPA axis in the Cluster B personality disorders may reflect either underlying affective disorder or exposure to trauma.

Suicide

A mechanistic neurobiological understanding of suicide remains out of reach. Most of the work to date has been an effort to identify biological correlates of psychosocial risk factors. A limited amount of data suggests that self-injurious behavior in personality disorder patients is related to serotonergic

abnormalities. New et al. (1997) found that suicidal and self-injurious behavior was associated with blunted prolactin and cortisol responses to D,L-fenfluramine. In a separate study, those with both impulsive and premeditative self-injury were found to have blunted prolactin response to D-fenfluramine compared with normal subjects, suggesting postsynaptic 5-HT receptor downregulation (Herpertz et al. 1995). However, several recent studies have implicated increased 5-HT_{2A} receptor binding in suicide and impulsivity, including studies of patients with BPD (Soloff et al. 2007). These results support a possible antisuicide effect of chronic antidepressant treatment and/or atypical antipsychotic drugs.

Suicide victims have increased CRH and vasopressin immunoreactivity in the brain, implicating biological mediators of emotional or social motivation in successful suicide (Merali et al. 2006). This important finding provides biological confirmation of data from psychological autopsies of suicide victims; recent social stress is a potent risk factor for suicide. The mechanism whereby environmental stress and the ensuing stress response increase the probability of a suicidal act is not yet identified.

Predictions and Limitations of the Model

One important prediction of our model is that a problem with representation would go on to affect complex processes that rely on representation, such as metarepresentation and/or motivation. The clinical implication would be that patients with working memory deficits might also be expected to additionally exhibit social or emotional deficits. This notion is supported by the high rates of Axis I–Axis II comorbidity in the clinic and the tendency for these comorbidities to occur across cluster categories. The other important clinical implication is that the circuits that are affected in personality disorder are the same circuits that are affected in Axis I disorders such as schizophrenia, anxiety, and depression. This is reflected in ubiquitous Axis I–Axis II comorbidity.

Another important prediction of our model is that the array of neurobiological deficits in clinical patients may be quite complex, and simple models of personality psychopathology based on "limbic hyperreactivity" or "hypofrontality" fail to account for prominent symptom classes such as disturbed sense of self or dissociative symptoms. With regard to these specific symptoms, there may be some benefit in looking outside psychiatry in fields such as learning disorders, which have focused on the parietal cortex as a biological mediator and so-called *metacognition* for therapeutic approaches. Although it is often stated that emotional lability is *the cause* of the unstable sense of self and others found in the Cluster B personality disorders, this has not actually been proven to be true. We would argue that it is plausible that the opposite mechanism may be equally valid, that inaccurate or distorted social cognition/motivation could result in emotional instability. This remains a testable hypothesis.

A model should be able to make quantitative predictions. Our model is clearly not yet quantitative, although it is compatible with a computational approach. For this reason, it remains a *heuristic* model of personality disorder. Brain/neuron-based computational models of personality disorder are not yet available for research purposes but may prove to be useful, if not *absolutely necessary,* to develop more sophisticated, reliable, and effective approaches to neuropsychopharmacology in this population.

Finally, we have also not focused on precise mechanisms of development and change. Although the current emphasis on regional functional brain imaging has resulted in canonization of the lesion model of psychopathology, time may prove this overemphasis to have limits. Careful examination of the literature also reports *positive* changes in personality disorder–related behavior after frontal head injuries (Labbate et al. 1997). Findings such as these call into question the validity of lesion-based models. They also suggest that not-yet-identified compensatory mechanisms in neural network function, rather than restoration of a "lesion," may play a role in both spontaneous (without therapeutic intervention) or therapeutically induced remission from personality disorder.

CONCLUSION

Meaningful progress in our understanding of the neurobiology of personality disorders brings hope that in the near future this understanding will result in substantive progress in treating these disorders. Clinicians recognize that these disorders can represent serious mental illness, with potentially crippling disability, disproportional public health care expenditure, and tremendous suffering. That progress in our understanding of the neurobiology of personality disorder comes in parallel with growing sophistication of both the basic and clinical neurosciences means that old conceptualizations must be challenged and tested. One advantage of a non-symptom-based heuristic is that the conceptual dissonance caused by the natural overlap of Axis I and Axis II disorders is deemphasized. In other words, this model highlights the biological overlap between these two subclasses of disorders. While previous symptom-based heuristics remain valid, we hope that this one raises new and fruitful questions.

Chapter 52. Neurobiology of Childhood Disorders

NEUROBIOLOGY OF CHILDHOOD DISORDERS: INTRODUCTION

Mental health sciences witnessed a paradigm shift in the late twentieth century through the influence of three research themes. First, a focus on biology emerged following changes in psychiatric nomenclature and psychopharmacology. Second, advances in neuroscience provided heretofore unseen insights on the relationship between neural and information-processing functions, paving the way for a clinical neuroscience approach to mental illness. Third, the school of developmental psychopathology emerged, based on the recognition that most chronic mental illnesses have their roots in childhood. The current chapter, which focuses on the biology of childhood mental disorders, integrates these three themes. Given the breadth of work in each area, let alone the combination of the three, this chapter cannot provide a comprehensive review. Rather, I summarize major themes while providing illustrative examples from research on specific disorders.

In this chapter I present data on nine families of disorders: 1) pervasive developmental disorders (PDDs) such as autism, 2) schizophrenia and other psychoses, 3) learning disorders such as dyslexia, 4) disruptive behavior disorders (DBDs) and attention-deficit/hyperactivity disorder (ADHD), 5) bipolar disorder, 6) major depressive disorder (MDD), 7) obsessive-compulsive disorder (OCD) and Tourette's syndrome, 8) posttraumatic stress disorder (PTSD), and 9) pediatric anxiety disorders. Aspects of clinical presentation and therapeutics are reviewed in other chapters.

The chapter unfolds in four sections. The first section presents principles that provide a framework within which current biological research can be placed. The second section reviews current approaches in genetics research, which raises questions on the manner in which genes ultimately influence behavior emerging in a developmental context. In the third section, data on information-processing functions are reviewed, considering data from cognitive and affective neuroscience. These data suggest that specific neural information-processing pathways might provide the conduit through which genes sculpt behavior as genes interact with the environment. The final section reviews data on brain circuitry structure, function, and modulation, with a strong focus on brain imaging.

INTEGRATION OF DEVELOPMENTAL PSYCHOPATHOLOGY AND BIOLOGY

Virtually all chronic mental disorders are conceptualized as disorders of brain maturation. This view emerged from an integration of research in epidemiology and neuroscience. From the epidemiological perspective, the school of developmental psychopathology recognizes that diverse behaviors show consistent, robust patterns of change as children mature through adolescence (Rutter et al. 2006). Marked individual variability results from differences in the timing of these changes, revealing child-specific risks. From the neuroscience perspective, adult patterns of information processing emerge from development, since the immature brain is uniquely susceptible to both genetic and environmental influences (Nelson et al. 2002). Individual variability reflects variations in the timing of these influences. Together, this literature suggests that chronic psychiatric disorders emerge from the effects of genes and the environment on brain development.

Despite the insights emerging from these breakthroughs, research on the biology of pediatric mental disorders has proceeded less quickly than research on adult mental disorders. This discrepancy has

resulted from many factors, including the dearth of experienced researchers, the complex ethical issues confronting efforts to launch such studies, and the inherent difficulty of assessing both behavior and biology in the context of development. Due to these limitations, enthusiasm has emerged from avenues outside of biological research with children.

Epidemiology

Developmental psychopathology, as a distinct theoretical school, emerged following changes in psychiatric nomenclature in the 1970s. The advent of a standard nosology set the stage for longitudinal and family-based research. Armed with new assessment techniques, large cohorts of children received serial, standardized psychiatric assessments over time, beginning in the school age years and spanning into adulthood. Three key insights emerged from this work:

1. Longitudinal community-based research demonstrated the surprisingly high prevalence of pediatric mental disorders, revealing as many as a third of individuals to be affected before adulthood (Rutter et al. 2006). Interestingly, many common conditions were shown to be transient in children followed longitudinally, whereas rarer disorders, such as the PDDs, typically were persistent. Nevertheless, the roots of chronic psychopathology were shown to lie both in rare, persistent disorders and in the exceedingly common, typically transient conditions, such as the anxiety disorders. Longitudinal studies showed that most adult mental disorders arose in individuals who had manifest psychopathology as children, typically in the most common forms of pediatric mental illnesses. This truism held for virtually all forms of psychopathology.
2. Longitudinal family-based research confirmed these observations while establishing the familial nature of mental illnesses. Again, for most psychopathology, including PDDs, psychosis, mood disorders, anxiety disorders, and DBDs, disorders were shown to be developmental and family based (Caspi and Moffitt 2006; Dickstein and Leibenluft 2006; Merikangas et al. 1999; Rutter 2005; Weissman et al. 2006). Offspring of adults with various mental syndromes face a high risk for psychiatric illness. Moreover, even in children free of overt psychopathology, signs of risk are manifest in patterns of information processing (Merikangas et al. 1999). Finally, manifestations of risk change developmentally. For example, offspring of parents with MDD might show high rates of anxiety as opposed to MDD, whereas offspring of parents with bipolar disorder might show high rates of MDD rather than mania (Dickstein and Leibenluft 2006). As some children of MDD parents with anxiety disorders mature, they manifest MDD, whereas some children of parents with bipolar disorder ultimately manifest bipolar disorder (Rutter et al. 2006).
3. A focus on risk factors for mental illness emphasized the need for research on biology. Although longitudinal studies established the clear relationship between social risk factors (e.g., poverty) and psychopathology, a surprisingly high number of children were resilient (Rutter 2000). The recognition of marked individual differences in susceptibility to risk raised questions on the role of biology in the modulation of risk. Moreover, some biological factors were shown to predispose toward pediatric mental illness even in the absence of social risks. Initial work emphasized the strong relationship between epilepsy and mental disorders, particularly the PDDs (Rutter 2005). These observations soon extended to a wealth of other neurological conditions, such as brain injury manifesting either in overt developmental delays or in more subtle indicators of brain dysfunction. With continued refinements, epidemiological research extended to focus on ever-subtler developmental influences. This included research relating teratology, such as from maternal smoking, to pediatric DBDs, as well as studies linking various perinatal immunological or nutritional compromises to psychosis (Rutter et al. 2006). Finally, findings from work that focused on very young children, a group thought to be particularly susceptible to environmental and social influences, further contributed to this focus on early biology. Temperamental profiles, such as behavioral inhibition, were identified in these studies. Such profiles were ultimately shown to be stable across many environments, influenced by genes, and associated with biological profiles (Fox et al. 2005).

Developmental Neuroscience

Advances in developmental neuroscience proceeded in parallel with advances in clinical

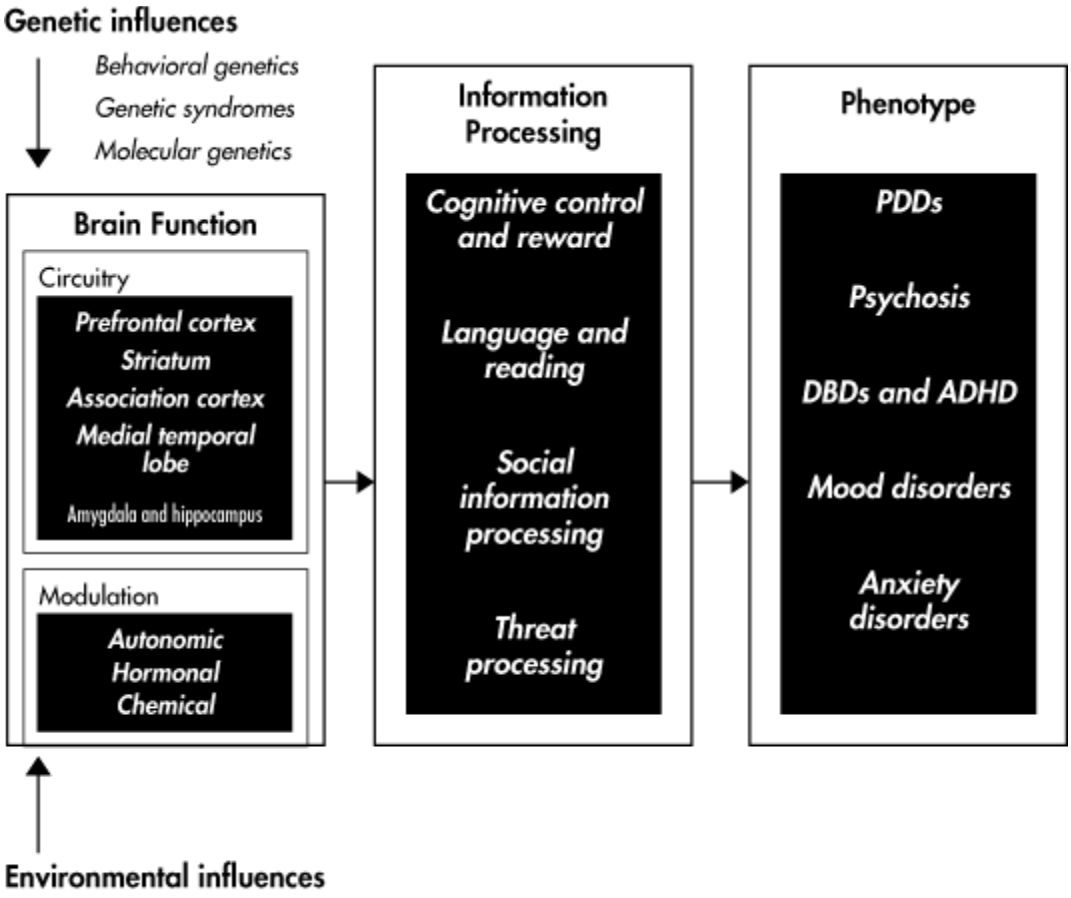
conceptualization. Considerable work prior to the 1980s had established the importance of developmental events for the foundation of healthy neurological function. Some of the strongest evidence in this regard focused on relatively extreme manipulations involving events that seemed relatively removed from those implicated in developmental psychopathology. For example, work on the visual system firmly established the presence of age-related differences in susceptibility to alterations in environmental input: complete deprivation of visual input to one eye early in life produced long-term robust effects on visual function. Similarly profound deprivations in early-life social experience had demonstrated the malleability of emotional functioning. Work in the final decades of the twentieth century revealed the broader applicability of the developmental neuroscience approach. Even relatively subtle variations in developmental events were shown to produce robust changes in behavior that appeared relevant to emerging views of psychopathology.

One relevant example emerged through research using relatively subtle manipulations of the rearing environment (Meaney 2001). This work demonstrated long-term effects on emotional systems. Much of the early work in this area relied on experiments with rodents, where pups and dams were separated for brief periods of time. Such manipulations produce lifelong alterations in the pups' response to stress. The robust, replicable nature of these findings facilitated work on the neural architecture mediating these effects: changes in glucocorticoid receptor biology, with reverberating effects on measures of information processing and threat-response behavior, instantiated in the hypothalamic-pituitary-adrenal (HPA) axis, the medial temporal lobe, and the prefrontal cortex (PFC). As this work continued, the molecular underpinnings were revealed, involving epigenetics. Finally, studies in both humans and nonhuman primates began to demonstrate parallel effects and associations (Gross and Hen 2004). Enthusiasm for extensions to research on the biology of pediatric mental disorders soon followed.

Another relevant example emerged from work on genetic manipulations in mice. Research throughout the 1980s had firmly established the modulatory role of serotonin (5-hydroxytryptamine; 5-HT) over complexly organized high-level behaviors, such as those engaged by threats and danger (Gross and Hen 2004). For example, deletion of the 5-HT type 1A (5-HT_{1A}) receptor in the mouse altered the threshold for engaging in these behaviors. Further research elucidated the developmental context in which these effects emerge: 5-HT_{1A} receptor deletion in the mature mouse produced no detectable effects on threat-response behavior, whereas transient deletion only in the immature mouse produced a long-lasting effect well into adulthood, even in mice with transiently abnormal 5-HT_{1A} activity as juveniles and normal 5-HT_{1A} profiles as adults. As with work on the HPA axis, studies in primates complemented these findings. Given the role of the amygdala in rodent fear, for example, studies in nonhuman primates examined developmental influences on amygdala function. This work showed that the effects of amygdala lesions on fear varied as a function of development (Prather et al. 2001). As work from these and other projects accumulated, enthusiasm for extensions to developmental psychopathology grew.

Endophenotypes

Initial attempts to integrate findings from clinical and basic science called attention to significant hurdles complicating such integrative research. Primary among these were questions on the validity of clinical phenotypes. Initial questions arose from limitations in the assessment techniques, related to complications in combining information from multiple informants and the need to ground assessments of pathology in understandings of normal variations in behavior. However, even after these problems were solved, major questions on phenotypes persisted. For example, studies in the PDDs found that relatively few relatives of children with autism manifest overt diagnoses of autism, yet such relatives often manifest subtle variants of core symptoms in autism, such as mild problems in language or social relatedness (Rutter 2005). Similarly, studies in MDD found that many children at high-risk for MDD were free of psychopathology but exhibited subtle subclinical perturbations in their responses to



threats or rewards (Grillon et al. 2005). These observations elucidated the need for alternative approaches to phenotype classification in children, given demonstrations of changing manifestations in risk across the life span.

A focus on endophenotypes provided the opportunity to ground classifications of children in emerging understandings of neuroscience (Gottesman and Gould 2003). Thus, potential endophenotypes were selected based on understandings of brain–behavior relationships. As the sophistication of these understandings grew, the applicability of this perspective increased, ushering in new frameworks for the conceptualization of developmental psychopathology and its relationship to biology.

Current Frameworks

Figure 52–1 illustrates one current framework for conceptualizing the biological correlates of pediatric mental illnesses. Material covered in the remainder of this chapter can be organized around this figure. Thus, the origins of mental illness are shown on the left side of this figure, where genetic and environmental events impinge on development, ultimately through effects on brain development. In this framework, considering individual disorders, distinct genetic and environmental effects produce effects on distinct but overlapping neural circuits, accounting for the specific manifestations of pediatric psychopathologies. For some conditions, these effects are likely to be overwhelmingly genetic, at least in their earliest inception. For other conditions, these effects are likely to involve stronger environmental components.

FIGURE 52–1. A conceptual framework for biological research.

Copyright © American Psychiatric Publishing, Inc., or American Psychiatric Association, unless otherwise indicated in figure legend. All rights reserved.

This figure illustrates a framework in which to place current research on the biology of pediatric mental syndromes. The framework attempts to link understandings of brain function to clinical categorization by examining the relationship between variations in brain function and specific information-processing functions. ADHD = attention-deficit/hyperactivity disorder; DBDs = disruptive behavior disorders; PDDs = pervasive developmental disorders.

A major challenge is to map the manner in which variations in brain function (shown on the left side of the figure) give rise to variations in psychopathology, represented as phenotypes (shown on the right side of the figure). For studies in juveniles, the magnitude of this challenge is particularly large, given the need to delineate a constantly changing relationship between brain function and behavior. One approach delineates brain–phenotype relationships by focusing on measures of information processing, as depicted in the middle box of Figure 52–1. Research that connects elements of information processing (the middle box in the figure) to the clinical phenotypes (the box on the right) capitalizes on the success of neuroscience research linking understanding of brain function and information processing, thus connecting the middle and the left boxes in Figure 52–1. Taken together, this research allows clinical–neuroscience integration.

The remainder of this chapter reviews the manner in which ongoing research on childhood mental disorders maps relationships between genes and the environment, through measures of brain function and associated information-processing profiles, onto clinical phenotypes. This review is organized around three sections. For the first two sections, the review focuses more on aspects of methodology than on specific pediatric mental disorders, discussing findings in specific disorders only for illustrative purposes. Thus, the initial section, on genetics, focuses more on available methods than on findings in one or another disorder. Similarly, the next section, on information processing, focuses on the four cognitive domains depicted in the middle box of Figure 52–1 linked to distinct neural circuitry function, again without comprehensively reviewing findings in specific disorders. Greater depth is provided, however, in the final section ("Brain Function"). Given the promise of brain imaging, this section summarizes findings across diverse clinical domains, considering conditions broadly grouped into five categories: PDDs; psychosis; DBDs and ADHD; mood disorders; and anxiety disorders.

Ultimately, this work is likely to lead to conceptual changes, as nomenclature moves toward classifications based on pathophysiology. Scientific and practical complications limit efforts to ground such research in studies of juveniles. Nevertheless, evidence delineating the importance of the developmental approach emphasizes the importance of addressing these complications.

GENETICS

As indicated in Figure 52–1, three research areas document genetic influences on developmental psychopathology: behavioral genetics, specific genetic syndromes, and molecular genetics.

Behavioral Genetics

Observations of strong, consistent familial aggregation encouraged efforts to identify genetic and environmental correlates of psychopathology. As with most research on pathophysiology, this work began with studies based in adults. Such work showed that retrospectively assessed factors operating in childhood modulated the impact of genetic and environmental effects on risk for psychopathology. This generated enthusiasm for implementing such studies directly in children.

Initial results in children have demonstrated both commonalities with and differences from findings of research in adults. As in adult disorders, wide variability exists for the pediatric mental disorders in the contributions of environmental and genetic effects. Thus, some disorders, particularly PDDs and ADHD, have been shown to be overwhelmingly genetic, whereas most common disorders are influenced heavily by nonshared environmental effects (Thapar and Rutter 2008). Certain DBDs have emerged as the rare examples of conditions with strong shared environmental influences. As in adults,

these data emphasize the importance of genetic and environmental contributions.

Findings in children have also generated novel insights, relative to studies in adults. For example, genetic contributions to a disorder in adulthood (e.g., MDD) might be shared with genetic contributions to a different type of disorder in childhood (e.g., anxiety) (Thapar and Rutter 2008). Alternatively, some disorders classified as nosologically similar might exhibit distinct genetics, such as has been shown for some forms of conduct disorder. Behavioral genetics research in juveniles has also benefited from the opportunity to directly assess environmental contributors to psychopathology, going beyond indirect statistical measures. Such work has emphasized the role of gene–environment interactions, operating in a developmental context, to shape risk for many of the more common disorders (Thapar and Rutter 2008). These include DBDs, mood disorders, and anxiety disorders.

Genetic Syndromes

Interest in molecular genetics has been stimulated further by research demonstrating behavioral correlates of developmental syndromes associated with specific genetic alterations. Some chromosomal syndromes either are relatively common (e.g., Down syndrome) or are associated with extreme alterations in behavior (e.g., Lesch-Nyhan syndrome). With these conditions, focus on the psychiatric concomitants emerged shortly after the syndromes were first described, and these features were attributed at least partially to consequences of intellectual disability, given its recognized role in shaping risk for psychopathology. Accordingly, few implications emerged for understandings of psychopathology as typically manifested in the community.

More recently, continued advance in molecular genetics techniques has generated interest in a wider array of developmental syndromes and their relevance for psychopathology in the community (Thapar and Rutter 2008). For these conditions, insights on gene–behavior associations have begun to broadly shape thinking on developmental psychopathology. For example, deletion at chromosome band 22q11.2 gives rise to velocardiofacial syndrome (VCF), which manifests in cutaneous, cardiac, and neurological changes. VCF is associated with a high risk for psychosis, generating interest in the role of genes lying within this region of chromosome 22. Suggestive findings in adult patients with schizophrenia, in the absence of VCF, increase interest in this area, as do recent brain imaging studies on neural correlates of VCF. Similarly, William's syndrome results from a deletion on the long arm of chromosome 7 (band 7q11.23). This syndrome also presents with a unique behavioral pattern, characterized by intellectual deficits and high levels of anxiety but surprisingly high levels of sociability. Here, too, findings using brain imaging technology raise questions on the role of chromosome 7 in the regulation of social experience in behavior.

For these two syndromes, VCF and William's syndrome, the presence of intellectual deficits raises questions about the role of indirect mechanisms contributing to the observed psychiatric profiles. However, studies in other single-gene disorders that typically manifest in childhood, such as 21-α-hydroxylase deficiency, have generated further interest in understanding the role of specific genes in shaping behavior across development (Ernst et al. 2007). As reviewed elsewhere (Thapar and Rutter 2008), considerable other research in a range of genetic disorders has delineated the promise of this approach. Finally, other work in sporadically appearing cases of conditions that are typically highly familial has informed targeted focusing on specific genes, as illustrated in recent work on Tourette's syndrome (Abelson et al. 2005). Alternatively, work in highly familial forms of language dysfunction also has led to the identification of novel genes.

Molecular Genetics

Much like research among adults, studies in children have begun to rely on the techniques of both genetic linkage and genetic association to delineate the role of specific genes in relatively common psychiatric disorders ascertained in the community or the mental health clinic. As a rule, work using the technique of genetic association generally has fared better in generating replicated findings,

though suggestive findings have emerged from linkage studies focused on PDDs and dyslexia. Reviews of these findings can be found elsewhere (Faraone and Khan 2006; Gupta and State 2007; Swanson et al. 2007; Thapar and Rutter 2008).

The best-replicated work in genetic association derives from studies of ADHD, where research in many thousands of patients implicates genes for various monoamines in the disorder (Faraone and Khan 2006; Swanson et al. 2007). As with all association studies, work on ADHD is facilitated by research on pathophysiology implicating one or another pathway in the disorder, where the robust efficacy of psychostimulants has provided important clues. Associations with both the dopamine$_4$ (D_4) receptor and the dopamine transporter appear reasonably well replicated.

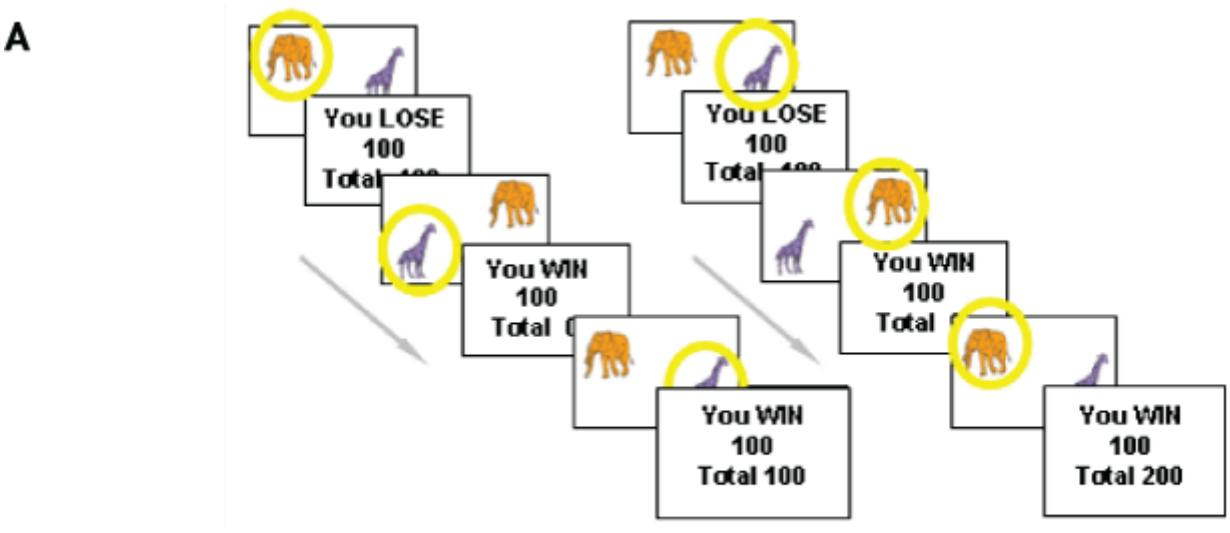
Similarly strong evidence has emerged in association studies of PDDs and OCD, with work on 5-HT genetics extending earlier studies on 5-HT neurochemistry and therapeutics in both of these disorders (Gupta and State 2007). For other disorders, findings generally are less well established. Nevertheless, a steady stream of biological clues has provided many targets for a range of clinical phenotypes in children. Thus, brain-derived neurotrophic factor has been implicated in pediatric MDD; the glutamate transporter gene solute carrier family 1, member 1 (*SLC1A1*) gene has been implicated in OCD; and various 5-HT–related or HPA-related genes have been implicated in one or another anxiety phenotype.

Across genetic research on children, the magnitude of association generally has been small, rarely increasing the risk for one or another psychopathology by more than twofold (Thapar and Rutter 2008). This suggests that pediatric mental illnesses arise from complex cascades of genetic and environmental events. Such realizations have encouraged efforts to map these specific cascades, as exemplified by recent work on gene–gene interactions in risk for adverse reactions to trauma and by recent work on gene–environment interactions in risk for DBDs and MDD. For example, Caspi and colleagues mapped one such interaction in research conducted with the so-called Dunedin cohort from New Zealand, one of the best-characterized longitudinal, epidemiological samples (Caspi and Moffitt 2006). In this cohort, environmental risk for conduct problems and associated DBDs was modulated by genetic variation in the gene for monoamine oxidase A, a gene that had been selected for study based on earlier work in a family with a rare deletion of this gene. Such findings have generated enthusiasm more broadly in efforts to map the complex way in which individual genetic and environmental events shape risk.

INFORMATION PROCESSING

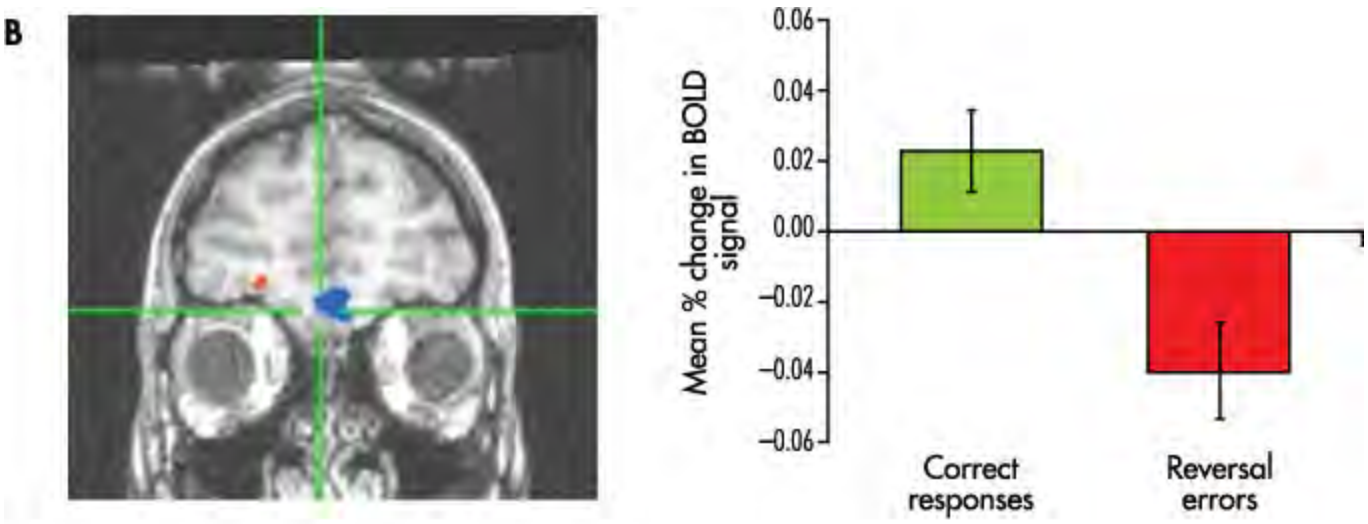
The current framework rests heavily on research examining information processing, because studies in this area play a unique role in the integration of research on brain function and phenotypes, as shown in Figure 52–1. Work in this area relies heavily on studies from the fields of cognitive and affective neuroscience. Tools from these fields index observable variations in behavior, and these behaviors are selected based on knowledge of the underlying neural architecture and associated information-processing functions. If variations in these behaviors can be linked to clinically relevant phenotypes, it is possible to bridge research on brain function and its influence by genes or the environment with research on clinical phenotypes. Moreover, this research can be based in a developmental context, allowing changes in such behaviors to be mapped to changes in associated brain function.

Given the explosion of work in this area, the current chapter cannot exhaustively summarize all aspects of the relevant work. Rather, I highlight illustrative examples where information-processing functions with known neural architecture have been most consistently linked to childhood mental disorders. This section focuses on the four information-processing functions delineated in Figure 52–1: cognitive control and reward, language and reading, social information processing, and threat processing. For each of these four functions, the section summaries prior research on the neural



architecture of each function before highlighting key findings relating the function to psychopathology.

Cognitive Control and Reward



Research on choice behaviors in the context of competing goal demands implicates a specific neural circuit in decision making. Much of this work relies on experimental paradigms in which a subject must make a difficult choice, perhaps because one or another response is rendered pre-potent due to the rapid pace of the task or because the appropriate choice is ambiguous, as exemplified by the "stop" task, various Go/No-Go paradigms, and the flanker tasks. In these tasks, behavior is thought to be regulated by components of the PFC that represent aspects of the task's rules, whereas interactions between the PFC and striatum facilitate efforts to adjust behavior when task contingencies change (Blair et al. 2005). This occurs, for example, on events with high conflict, such as "stop" trials on the stop task. Children with a select group of pediatric psychopathologies exhibit perturbations on these tasks, providing a strong foundation for integration of clinical and research perspectives in these disorders. Thus, this research implicates PFC–striatal dysfunction in ADHD, PDDs, and OCD while distinguishing these conditions from non-OCD anxiety disorders or MDD, where performance is intact (Nigg 2007; Swanson et al. 2007).

The affective salience of these so-called cognitive control tasks can be augmented by manipulating the costs and benefits of one or another decision. For example, a subject might be rewarded on a select series of trials for a correct response or punished on other trials for an incorrect response. The difficulty of the task can be increased by focusing on a child's ability to alter responses as task contingencies change. Figure 52–2 illustrates one such task, based on the so-called response reversal paradigm, wherein a subject is required to select one of two objects to obtain rewards in the context of continually changing contingencies (Budhani et al. 2007). This task engages brain systems that facilitate adaptive behavior required when task rules change, such as when contingencies reverse. As shown in the figure, in the context of the need to reverse choices, these paradigms influence activity in medial PFC. Other work shows that children with DBDs and related disorders perform poorly on such tasks (Blair et al. 2005; Nigg 2007; van Goozen et al. 2007). Thus, through the use of these and other manipulations, considerable research implicates PFC–striatal circuitry in reward-related behaviors, ADHD, trauma, and mood disorders.

This figure shows details of a probabilistic response reversal task **(A).** In this task, subjects begin by trying to select a rewarded target (e.g., the giraffe) while avoiding a punished target (e.g., the elephant). Following acquisition of this "giraffe-reward" rule, the contingencies change in the reversal phase of the task. Functional magnetic resonance imaging **(B)** demonstrates that during this learning-related process, decreased engagement of the medial prefrontal cortex (PFC) occurs in trials when adult subjects commit errors by failing to learn the new "elephant-reward" rule. Deficient medial PFC engagement on such tasks in some pediatric mental syndromes might reflect a role for perturbed medial PFC function in the condition. BOLD = blood oxygenation level–dependent.

Language and Reading

The effects of brain lesions on cognition generated early interest in elucidating relevant neural pathways. The development of language abilities and the development of reading abilities represent two of the most significant aspects of cognitive development, and considerable work in cognitive neuroscience examines the underlying circuitry.

Research on language development has pursued diverse avenues. One set of studies extended observations in children with specific language impairment. This condition is hypothesized to result from a relatively specific deficit in decoding subtle temporal variations in phonemes. Consistent with this possibility, focused training designed to compensate for this specific deficit was shown to remedy the language deficit in some children (Tallal and Gaab 2006). In other work, children with unusual familial forms of language dysfunction were found to exhibit a unique neural and molecular profile (Vargha-Khadem et al. 2005).

Research on both normal and abnormal reading abilities, as manifested in developmental reading disorder or dyslexia, has followed similarly divergent pathways. Considerable work with typically developing children has isolated the cognitive processes that provide foundations for successful reading. This work has delineated the typical development timing during which these processes mature, as well as the complex collection of brain regions required (Joseph et al. 2001). This provides

a rich backdrop against which to place dyslexia. A parallel series of studies implicates specific processes in reading disorders (Joseph et al. 2001). As with the work on specific language impairment, these insights have provided novel insights on treatments. Such treatments have been tailored to correct relatively specific core underlying deficits in the relevant psychological process. In emerging work, this model of developing remedial training after identifying a specific deficit in a relatively pure cognitive disorder has been extended to other disorders, such as ADHD, that are less typically considered purely cognitive conditions.

Social Information Processing

Perturbations in social relationships represent core features of many disorders. Recent developments implicate specific neural circuitry in the regulation of human interaction, providing a rich context in which to place research on developmental psychopathologies. In this area, the most consistent findings emerge in studies of PDDs, DBDs, traumatic exposure, and bipolar disorder.

Major disruptions in social relatedness represent one of the three key features of PDDs, along with deficits in language and stereotypical behaviors. Given the profound nature of clinical deficits, it should come as no surprise that children with PDDs also exhibit deficits on social neuroscience paradigms (Rutter 2005). For example, one set of studies, which relied on examinations of eye-scanning patterns, showed that individuals with PDDs attend to distinctly different social cues compared with healthy individuals, with very large effect size differences (Volkmar et al. 2004). Similarly, individuals with PDDs also have been shown to exhibit deficits on so-called theory-of-mind tasks that require the decoding of complex social motivations of peers. Both areas rely on relatively complex aspects of social information processing. Studies of more elementary processes, such as the labeling of face emotions, also have revealed deficits in children with PDDs.

Although perturbed social information processing might be expected in PDDs, other syndromes associated with less severe social deficits also have been linked to poor ability to decode social signals. Such deficits are likely to arise from many different pathways, as they have been found in children exposed to traumatic circumstances, which might lead to environmentally mediated deficiencies, as well as in children with psychopathy, a condition where the deficit in social processing is thought to result from genes (Blair et al. 2005). Children with bipolar disorder also show such deficits (Leibenluft et al. 2003). Of note, these deficits are relatively specific to this family of conditions; children with ADHD, other DBDs, anxiety disorders, and MDD show no such deficits.

Threat Processing

Research on threat processing has benefited from advances in affective neuroscience, a field focused specifically on the role of emotionally salient events in regulating the processing of information. Threats have been shown to heavily influence many aspects of behavior, through effects on diverse information-processing functions. Some of the most consistent findings have emerged in research finding that threats show a greater capacity than neutral material to influence attention (Pine 2007). For example, threats are recognized more quickly than neutral stimuli in some paradigms, whereas they interfere more strongly than neutral stimuli in other paradigms. These effects have been mapped to specific neural circuits encompassing the amygdala and PFC. Most importantly, these paradigms have been used to differentiate children with various psychopathologies, particularly the anxiety disorders, in which threats exhibit a particularly marked effect on attention. This work has generated interest in the use of other paradigms, co-opted from basic science, which require coordinated engagement of the amygdala and PFC. For example, considerable work suggests that anxiety disorders reflect a perturbation in processes related to fear conditioning and extinction.

Work on other disorders emphasizes the effects of threats or other emotional stimuli on processes distinct from attention. For example, in work on MDD, effects appear larger in memory than in attention paradigms. Similarly, work on bipolar disorder has documented a range of perturbations in

threat-response behavior.

BRAIN FUNCTION

As shown in Figure 52–1, knowledge of brain function derives from research in two areas: functioning of relevant brain circuitry and modulation of this circuitry through autonomic, hormonal, and chemical influences. For studies in children, some of the most promising insights linking brain function to clinical phenotypes have emerged through research using brain imaging to examine circuitry. Research on modulation of circuitry has provided less profound influences on current clinical thinking. As a result, in the first portion of this section on brain function, I only briefly summarize research on brain circuitry modulation, whereas in the remainder of the section I provide a more detailed review of imaging studies in specific developmental psychopathologies. This review delineates relevant findings by focusing on normal development and the five classes of disorders illustrated on the right side of Figure 52–1, depicted as groups of phenotypes: PDDs, psychosis, DBDs and ADHD, mood disorders, and anxiety disorders.

Modulation of Circuitry

Autonomic, hormonal, and monoamine systems modulate activity in key neural systems, either when chemicals act directly on neural structures or when chemicals enable communication among components of circuitry-based feedback loops. These modulatory influences can be assessed by measuring variations in peripheral physiological indices. Considerable work in children relies on these measures, given ethical constraints on more invasive measures. Nevertheless, this chapter only briefly summarizes these findings. Work on modulation of circuitry has had a less profound influence on current clinical thinking than brain imaging research in recent years, because measures derived from imaging provide a more direct index, relative to measures of autonomic, hormonal, or monoamine system modulation, of neural system function associated with mental illnesses.

Autonomic Activity

Activity in the sympathetic and parasympathetic systems is influenced by the amygdala and associated systems. As a result, considerable work has attempted to infer the nature of individual differences in amygdala function through an examination of individual differences in autonomic parameters. Probably the most consistent findings in this area have emerged from research on the association between low heart rate and conduct problems in children (van Goozen et al. 2007). This association is thought to reflect blunted amygdala sensitivity to punishment cues, consistent with current models of some DBDs. Conversely, other work has linked elevated heart rate to various forms of pediatric anxiety, including behavioral inhibition, viewing these associations as a sign of amygdala hypersensitivity to threat (Fox et al. 2005; Pine 2007). Because these differences in heart rate could arise from differences in either parasympathetic or sympathetic systems, other work has used spectral analysis of heart period variability to draw inferences specifically on parasympathetic regulation. Findings in this area generally have been less consistent than findings linking differences in heart rate to differences in pediatric psychopathology.

Beyond work on cardiac activity, other research links childhood psychopathology to respiratory perturbation, extending work on the biology of adult panic disorder. Here, a consistent association has emerged between respiratory dysregulation and pediatric separation anxiety disorder, consistent with other work linking separation anxiety and panic disorders (Pine 2007). Of note, pediatric social anxiety disorder involves normal respiratory regulation, suggesting that individual anxiety disorders display unique biology.

While findings in this area have generated consistent interest in biological correlates, recent work has focused more closely on cognitive neuroscience than autonomic physiology. This provides a more direct measure of activity in neural systems that are thought to mediate observed associations

between autonomic physiology and psychopathology.

Hypothalamic-Pituitary-Adrenal Axis

Interest in the association between pediatric mental illness and HPA axis function follows from work relating variations in HPA activity of the rat pup to lifelong emotional response patterns (Gunnar 2003). As with work on autonomic function, the most consistent association has emerged in studies of DBDs, where a subgroup of children has been shown to exhibit low cortisol levels, possibly through the effects of the early-life rearing environment (Gunnar 2003; van Goozen et al. 2007). Consistent with this possibility, a recent randomized, controlled trial demonstrated an association between changes in DBD symptoms and increases in HPA axis activity (Brotman et al. 2007). Each of these findings is thought to reflect perturbed amygdala-based regulation of HPA axis activity. On the other hand, many other areas of research have found inconsistent associations between HPA axis activity and pediatric psychopathology. For example, work in MDD has found less consistent associations in children and adolescents, relative to the associations found in adults. This contributes to some questions on the utility of further work focused on the HPA axis in the absence of concomitant direct assessment of underlying brain system function.

Monoamine Function

Two findings have stimulated interest in monoamine function. First, considerable work implicates monoamines in adult disorders, and the developmental conceptualization of these adult psychopathologies encourages efforts to link pediatric syndromes to monoamine dysfunction. Second, effective psychotropic agents exert robust effects on monoamine systems. Despite consistent enthusiasm, it has been more difficult to implement work in children than in adults, given the limited availability of ethically permissible measures of central monoaminergic function.

Efficacy data in pediatric mood and anxiety disorders have generated interest in the serotonin (5-HT) and norepinephrine systems. The superior efficacy of the selective serotonin reuptake inhibitors compared with the tricyclic antidepressants has generated considerable interest (Emslie and Mayes 2001). Some suggest that the differing neurochemical profiles of these medication classes support a stronger role for 5-HT than for norepinephrine in pediatric syndromes targeted by antidepressants. Consistent with these suggestions, relatively few studies have documented associations between pediatric mental illnesses and individual differences in norepinephrine system functioning, although some work implicates the norepinephrine system in pediatric anxiety disorders (Pine 2007).

Considerable research implicates 5-HT dysfunction in pediatric mental syndromes. This includes most consistently PDDs, MDD, and DBDs (Birmaher and Heydl 2001; Rutter 2005; van Goozen et al. 2007). Work in this area has relied on a wealth of techniques, including assessment of peripheral 5-HT–related parameters such as whole-blood 5-HT or platelet 5-HT receptor profiles, cerebrospinal fluid 5-HT metabolite levels, and neuroendocrine assessment following administration of 5-HT agonists. One of the major questions emerging from this work examines the degree to which development impinges on the 5-HT–behavior association in humans, as it does in rodents and primates. Some physiology data suggest the presence of human developmental variation (van Goozen et al. 2007), and this is consistent with data documenting age-related changes in the adverse effects of treatment with selective serotonin reuptake inhibitors (Emslie and Mayes 2001). Nevertheless, it remains unclear how to extend such findings, given that positron emission tomography techniques that are currently used in research on 5-HT correlates of adult psychopathology are poorly suited for research with juveniles.

Work on the dopamine system has also generated consistent interest. The robust efficacy of the psychostimulants in ADHD and other DBDs indirectly implicates dopamine dysfunction in these conditions, as do the genetic association studies reviewed above. Preliminary positron emission tomography studies have provided further support (van Goozen et al. 2007). Work in this area also is

relevant for developmental conceptualizations of psychosis, which is rare before puberty, and of substance abuse, which typically intensifies in adolescence. Consistent with these age-related changes in risk, which have been attributed to maturation of the dopamine system, pharmacological studies have documented developmental changes in the response to dopamine challenge across the period around puberty (Spear 2000). Moreover, this work is also relevant for current models of psychosis implicating interactions between the dopamine system and glutamate systems. Much like developmental changes for dopamine response, the response to glutamate manipulations also has shown robust age-related changes (Olney 2003). Taken together, these data implicate developmental changes in the dopamine and glutamate systems, and their interactions, in developmental changes in risk for various mental disorders. However, as with work on the 5-HT system, complications in assessment of dopamine or glutamate function in children place limits on the degree to which future research can explore the neural basis of such developmental changes.

Brain Function: Circuitry Assessed With Brain Imaging

In many ways, biological research on childhood mental disorders has only recently begun to come of age, with advances in brain imaging techniques. For the first time, these advances have allowed a direct assessment of neural structure and functions in children with levels of temporal and spatial resolution appropriate for extensions to developmental work in animal models. This final section provides examples illustrating the manner in which brain imaging research facilitates integration of basic and clinical research.

Relevant examples have emerged from research in diverse areas, including both normal and pathological variations in behavior, utilizing diverse techniques, including structural and functional magnetic resonance imaging approaches (sMRI and fMRI), magnetic resonance spectroscopy (MRS), event-related potentials (ERPs), and quantitative electroencephalography. As with summaries of research in other areas, the current summary does not provide an exhaustive review but rather illustrates the manner in which research in specific clinical areas provides a bridge to findings emerging both from basic science research in rodents or nonhuman primates and from cognitive or affective neuroscience research in humans. I have organized this review in six sections, beginning with a summary of findings on normal development, followed by a review of key findings in the five clinical domains depicted in Figure 52–1.

Normal Development

The ability to directly visualize brain development has strengthened interest in developmental aspects of psychopathology. Recently emerging data chart robust changes in brain structure and function that extend from early childhood through late adolescence. These data support the view emerging from epidemiological studies that most chronic psychopathologies are disorders of brain development. These data also resonate with data in cognitive neuroscience delineating the developmental trajectories for specific information-processing functions.

Much of the interest in neural development comes from sMRI findings demonstrating robust regional variations across development in the architecture of gray and white matter. These variations follow three basic trends (Sowell et al. 2004; Steinberg et al. 2006; Toga and Thompson 2003):

1. Consistent with postmortem work in humans and basic science studies in nonhuman primates, human brain development as shown in sMRI exhibits a clear trend to progress from primary sensory or motor cortices, which mature early, to association cortices, which mature late. This is also reflected in the spatial posterior-to-anterior gradient on which the progression from primary to association cortex is arranged.
2. Human brain development shows a general trend for a plateau of gray matter volume in childhood, with a progressive reduction through adolescence in tandem with a parallel increase in white matter volume. Taken together, these two trends lead to a progressive increase in the white-to-gray-matter volume ratio,

consistent with a growing emphasis on integrative functions in the nervous system with maturation.

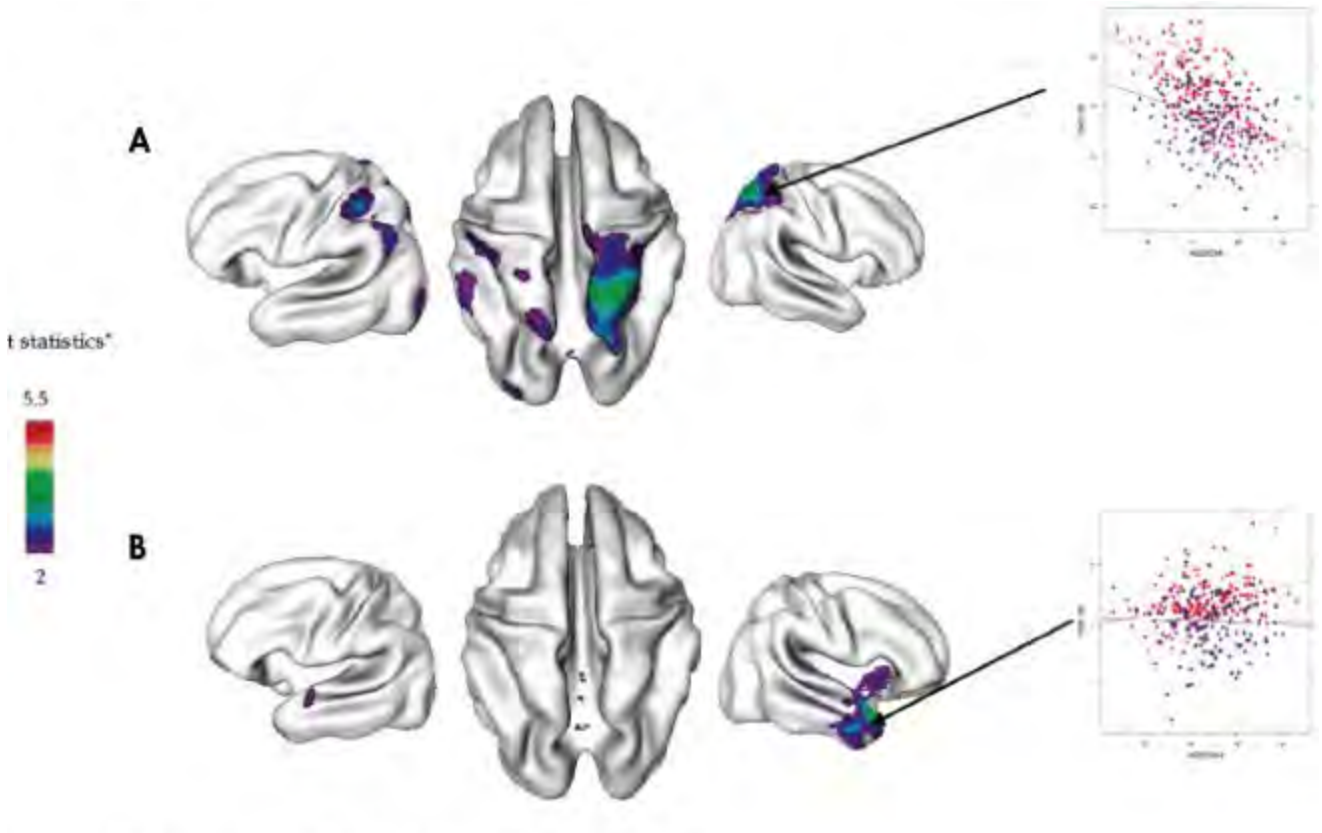
3. This general trend of a decrease in gray matter volume does not occur in all brain areas, as circuitry involving frontotemporal association cortices involved in linguistic maturation shows an opposite trend of increasing gray matter volume.

Taken together, these findings have generated considerable interest in mapping the relationships that such structural changes show with various measures of brain function, as manifested in direct measures of functional activity, as well as measures manifested in the environment, either on neuropsychological tests or in everyday experience.

Data from fMRI studies in developing humans generally confirm findings in sMRI studies (Nelson et al. 2002). Although far fewer studies rely on fMRI than sMRI, trends in fMRI research support the view of brain maturation as a process that extends well through late adolescence, with particularly later maturation of association cortices. Considerable interest has focused on functional aspects of medial temporal, striatal, and PFC development, given evidence from studies of behavior and sMRI studies suggesting these regions exhibit protracted development (Steinberg et al. 2006). Although many questions remain, the weight of the data suggests that each of these regions undergoes protracted development.

Pervasive Developmental Disorders

Current theories of PDD pathophysiology have been informed by data emerging using virtually every imaging modality. Together, this work extends insights emerging from other findings in epidemiology and cognitive neuroscience research. For example, early epidemiological studies raised questions on gross patterns of brain development in autism, based on perturbations in early-life head growth; sMRI studies confirmed that these differences in head growth are reflected in patterns of brain growth while also noting many regionally specific alterations in brain development in the cerebellum, amygdala, and other regions where one would expect perturbations, based on findings in cognitive neuroscience (Rutter 2005). These prior findings in cognitive neuroscience have generated specific interest in functional aspects of brain regions implicated in the regulation of social experience.



Ongoing fMRI research also successfully extends this work. For example, eye-movement data implicating perturbed attention control when processing social stimuli are consistent with fMRI studies documenting abnormal engagement of the amygdala, fusiform gyrus, and other components of neural circuitry implicated in the assessment of social significance (Volkmar et al. 2004). Similarly, cognitive neuroscience findings documenting perturbed abilities at imitation in PDDs have been extended through fMRI studies documenting abnormal engagement of so-called mirror-neuron systems implicated in imitation. Such fMRI work has unique advantages related to the excellent spatial resolution of the technique. However, the findings have also been extended through research using ERPs, with their superior spatial resolution, demonstrating the time course over which social processing dysfunction in PDDs manifests. Taken together, this work has generated considerable enthusiasm for refining our understandings of PDD pathophysiology by grounding these understandings in knowledge of neural development.

Psychosis

Data in child-onset schizophrenia uniquely demonstrate the advantages afforded by longitudinal examination of brain development, as is possible with sMRI. A central question emerging from early theories of psychosis focuses on contributions of static and dynamic neural developmental processes in changing manifestations of the illness. One of the most influential theories had suggested that a static temporal lesion interacts with dynamic changes in PFC structure emerging at adolescence to unmask a latent risk for psychosis. sMRI allows repeated assessment of brain structure across developmental periods with precise spatial localization of relevant static or changing morphology

(Greenstein et al. 2006). This provides an assessment of the degree to which the structures of specific brain regions change and adapt as children develop and show changing manifestations of the illness. Figure 52–3 illustrates the possibilities inherent with this technique, revealing the degree to which specific brain regions show distinct developmental topographies in typically developing children and children with schizophrenia. These findings document very large differences between children with overt manifestations of schizophrenia and healthy children. The demonstrable utility of this approach raises essential questions on applications to other forms of psychosis. For example, using this approach, it may be possible to capture emerging patterns of neural changes that place children at risk for psychosis before the full manifestation of pathological clinical syndromes. This may provide unique insights for both identification of at-risk individuals and targeted treatments designed to disrupt the ongoing pathological process before it has become fully entrenched.

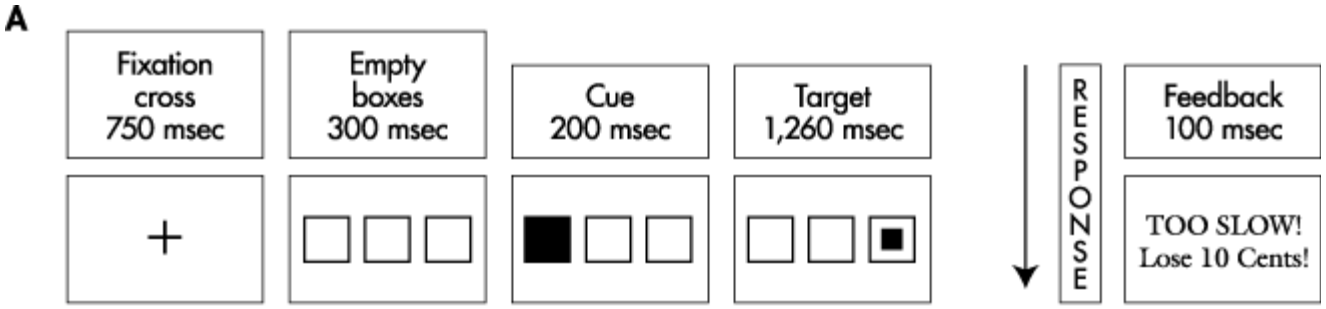
Disruptive Behavior Disorders and ADHD

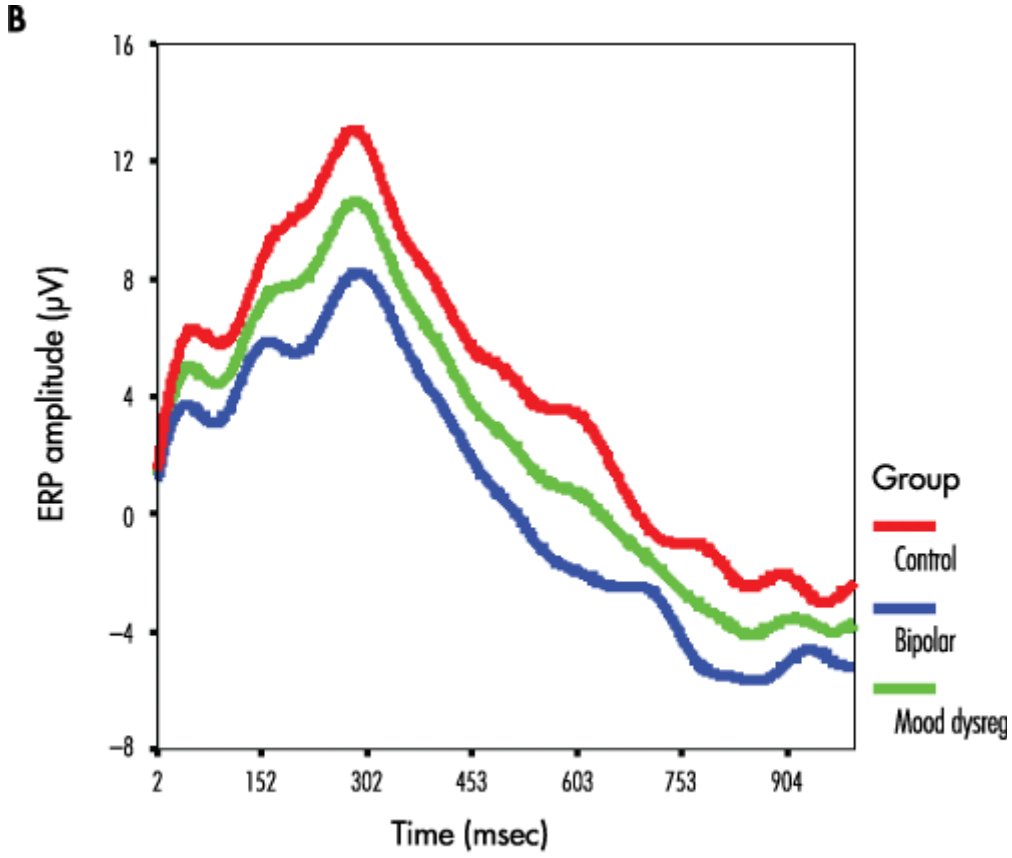
As with research on PDDs, work on DBDs and ADHD has relied on virtually every suitable imaging modality in research that directly extends findings generated in cognitive neuroscience. Without question, more research considers aspects of ADHD than DBDs, but important insights are beginning to emerge on differences among these disorders, each of which shows strong relationships in family-based and longitudinal research.

In research on ADHD, the most consistent approach extends findings emerging from research on cognitive control and reward processing. Studies in this area implicate a distributed neural circuit in the condition, encompassing the PFC as it connects with the striatum and cerebellum. sMRI studies provide some support for theories that implicate this circuitry in ADHD (Nigg 2007). However, overall reduction in brain volume represents a more consistent finding than selective reductions in these specific regions, independent of the more general reduction in brain volume. fMRI research provides more consistent support in that consistent dysfunction in the striatum and in the medial and ventral PFC emerges in this work, which supports findings from cognitive neuroscience research (Nigg 2007; Swanson et al. 2007). Data emerging from ERP research further refine understandings of the manner in which this circuit might be perturbed. Due to the superior temporal resolution of this technique, ERP data generate insights on the role of each PFC subregion and the striatum in perturbed cognitive control. As these findings have been steadily accumulating, questions have arisen concerning the degree to which one or another finding in brain imaging relates specifically to risk for ADHD, to overt manifestations associated with severity of the disorder, or to long-term trajectories of ADHD symptoms. The clinical utility of imaging approaches would be enhanced if data could be mapped onto distinct aspects of ADHD risk, presentation, or trajectory. Emerging data suggest that this may be possible.



Beyond research on ADHD, research data in other DBDs suggest that brain imaging measures might allow a refined categorization of behavior disorders (Blair et al. 2005; van Goozen et al. 2007). Although considerable research documents parallels in the neural correlates of ADHD and DBDs, emerging findings also suggest that a subgroup of children with DBDs can be differentiated from other children with DBDs and children with ADHD, based on functional aspects of brain circuitry engaged by emotionally salient events. One relevant theory in this respect suggests that a unique subgroup of children with DBDs exhibits a particularly poor prognosis and an unusually strong genetic component to their disorder (Blair et al. 2005). Current theory suggests that this profile is reflected in patterns of amygdala–PFC function during the evaluation of emotionally salient stimuli. Emerging brain imaging work generates findings generally consistent with this theory. As with work on ADHD, continued refinements of this approach may provide novel means for classifying pediatric DBDs based on associated neural circuitry dysfunction.

Mood Disorders



Data from cognitive neuroscience studies in pediatric bipolar disorder implicate two information-processing functions in the condition: cognitive control and social information processing. Given knowledge on neural correlates of these information-processing functions, data from brain imaging studies are consistent with these findings in cognitive neuroscience. Specifically, cognitive control has been linked to functional aspects of frontostriatal circuitry. Both sMRI and fMRI studies in pediatric bipolar disorder implicate this circuit in the condition (Dickstein and Leibenluft 2006; Leibenluft et al. 2003; Rich et al. 2006). Similarly, social information processing has been linked to amygdala function. Again, findings from sMRI and fMRI studies in pediatric bipolar disorder also support findings in cognitive neuroscience. Reduced amygdala volume in pediatric bipolar disorder is probably the best-replicated finding emerging from all of the imaging work in any pediatric mood disorder. Moreover, fMRI studies find evidence of enhanced amygdala activation, specifically under conditions where deficits in social information processing manifest.

Considerable controversy surrounds the diagnosis of pediatric bipolar disorder. Ideally, emerging findings in brain imaging will provide some insights helpful in resolving this controversy. Although imaging work is only beginning to speak to issues of classification, some evidence suggests that future work in this area may be helpful in refining understandings of bipolar phenotypes. Figure 52–4 illustrates one relevant finding using ERP technology (Rich et al. 2007). Much of the controversy in nomenclature concerns the classification of children presenting with marked irritability and hyperarousal in the absence of classic symptoms of mania, particularly distinct periods of elevated mood. Figure 52–4 shows that children presenting with these features can be differentiated from children with classic presentations of mania, whereas other findings from the same study also show that these children can be differentiated, using other ERP measures, from healthy peers as well as from children with classic bipolar presentations.

This figure shows P3 event-related potential (ERP) amplitude at the parietal Pz site during performance of a frustrating task. The task, which requires subjects to quickly identify a target, is made quite difficult, leading to frustration through frequent incorrect responses **(A).** As shown in **B,** when patients with bipolar disorder (*n* = 35; blue) make errors, ERP amplitude, phase-locked to these errors, is significantly lower than in both healthy peers (*n* = 26; red) (*P* <0.01) and peers with severe mood dysregulation but without bipolar disorder (*n* = 21; green) (*P* <0.05).

*Source.*Rich et al. 2007.

Imaging work on MDD also has generated consistent findings, again extending findings that have emerged from cognitive neuroscience studies based in the laboratory. Deficits in reward-related processes represent one of the most consistent correlates of MDD, in juveniles as well as in adults. Emerging fMRI data implicate perturbed striatal function in this information-processing profile (Forbes et al. 2006). Similarly, perturbations in memory, particularly for emotional stimuli, represent a second consistently manifested correlate of MDD across the age span. Considerable imaging work implicates the amygdala in emotional modulation of memory. Consistent with these data in healthy subjects, as well as with evidence of abnormal emotional memory in MDD, emerging imaging work suggests that emotional memory perturbations in adolescents with MDD are associated with amygdala-based dysfunction (Roberson-Nay et al. 2006). Such amygdala hypersensitivity has been attributed to increased afferent input from PFC-based glutamatergic neurons, possibly leading to excitotoxic processes over time. This view is supported by demonstrations of reduced amygdala volume in both pediatric and adult MDD.

Anxiety Disorders

Available imaging data demonstrate potential circuitry-based differences in the correlates of distinct pediatric anxiety disorders, consistent with data from family-based and longitudinal research. These data document one set of abnormalities in OCD, another set in pediatric PTSD, and a third set in other pediatric anxiety disorders.

Unique aspects of pediatric OCD relate to the distinct associations with basal ganglia dysfunction in OCD, dysfunction that is also thought to occur in other syndromes, such as Tourette's syndrome, that exhibit longitudinal and familial associations with OCD. Consistent with this view, the few available sMRI and MRS studies in pediatric OCD implicate perturbed frontostriatal circuitry in the condition (Rosenberg and Hanna 2000). Thus, pediatric OCD has been linked to altered striatal volumes, although the nature of these alterations varies across studies, as well as to signs of altered glutamate transmission. These findings are consistent with data in both ADHD and Tourette's syndrome, where other signs of altered basal ganglia dysfunction emerge.

Pediatric PTSD, in contrast, has been most consistently linked to abnormalities in specific components of the corpus callosum and PFC (De Bellis 2001). Neuroanatomical studies have documented reduced volume in various components of the corpus callosum, with the most consistent data implicating middle and posterior portions of this structure, contrasting with data in other disorders, such as OCD, where different regions show volume reductions. Relatively consistent findings have also emerged in research on the PFC, where various components show volume reductions. Other regions implicated include various aspects of posterior association cortex, such as the superior temporal gyrus, the pituitary, and the cerebellum, as well as overall reductions in brain size. Unlike in research on adult PTSD and in other anxiety disorders, however, medial temporal lobe structure and function generally appear intact in pediatric PTSD—despite a wealth of research attempting to document abnormalities in this region, based on the theoretical importance of this structure.

Finally, considerable research in anxiety disorders besides PTSD and OCD has documented abnormalities in brain circuitry encompassing the PFC and medial temporal cortex. As reviewed

elsewhere (Pine 2007), six studies have used face-viewing paradigms with fMRI to examine amygdala function in children with these conditions or behavioral inhibition, a major risk factor for these conditions. Five of the six studies documented signs of enhanced amygdala response to evocative faces, consistent with considerable work in adults with social phobia and with research linking both pediatric anxiety disorders and behavioral inhibition to adult social phobia. Other notable findings in these six studies include evidence of perturbed PFC activation as well as dysfunctional connectivity between the amygdala and PFC, findings that, again, are consistent with data from studies in adults.

FUTURE DIRECTIONS

As delineated in the current review, the stage has been set for major breakthroughs in research on the biology of pediatric mental disorders. The emerging advances in genetics, cognitive neuroscience, and brain imaging have provided the field with heretofore-unanticipated tools. These tools allow developmental scientists to chart brain–behavior relationships, and their underlying unfolding through genetic and environmental influences, in young children as they pass through each stage of development. The greatest excitement for future directions concerns applications of these tools. Thus, in each of the various clinical domains, considerable work remains to be done. Longitudinal research in young children is needed, documenting genetic and environmental influences on specific neural circuits and their chemical modulation. The development of these specific neural circuits must be mapped to specific information-processing functions, as delineated in cognitive and affective neuroscience. Finally, this mapping of brain function to information-processing indices must be linked to current conceptualizations of phenotypes.

CONCLUSION

The importance of biological research on childhood disorders has emerged largely from findings in epidemiology, basic science, and biological research among adults. Thus, epidemiology research has demonstrated the strong longitudinal and family-based associations between pediatric and adult mental disorders. Findings in basic science and in biological research among adults suggest that these associations between childhood and adult psychiatric syndromes emerge through the effects of perturbed brain development. This suggests that better knowledge about the nature of such developmental perturbations may provide novel avenues for treatments that interrupt processes contributing to chronic psychiatric disorders early in the pathophysiological process. However, realization of this goal will require the field to enhance understandings of the relationship between biological factors and development through studies implemented directly in children.

Chapter 53. Treatment of Depression

CHANGES IN CONCEPTUALIZATION OF DEPRESSIVE DISORDERS

The past 20 years have seen a shift in the way psychiatrists conceptualize depressive disorders. This evolution in our thinking has been stimulated by the results of epidemiological studies and of long-term clinical follow-up studies, investigations of spectrum disorders, advances in biological psychiatry, and results of large clinically focused national trials. In the past, major depressive disorder was viewed as episodic and self-limited. However, longitudinal observations of patients treated for major depressive disorder show that after recovery from an index episode of major depression, patients remain symptomatic about 60% of the remainder of their lives with another episode of major depression, minor depressive disorder, or subsyndromal symptoms of depression (Judd et al. 1998a). Data from the National Institute of Mental Health (NIMH) Collaborative Depression Study demonstrated that the recurrence rates of major depressive disorder are extraordinarily high over time: 60% at 5 years of follow-up, 75% at 10 years, and 87% at 15 years (Keller et al. 1982, 1984, 1992; Kupfer 1991).

Thus, the majority of people with major depressive disorder can be conceptualized as having a chronic illness with a dynamic course. This view of depression as a chronic and frequently recurring illness is a major paradigm shift. A second major shift in our thinking about major depressive disorder has revolved around the tension between conceptualizing the "depressions" as several discrete disorders (e.g., major depressive disorder, dysthymia, double depression, minor depression) versus considering major depressive disorder as part of a spectrum of mood disorders. In this schema, an individual may traverse over time between meeting criteria for major depressive disorder and meeting criteria for euthymia, minor depression, or subsyndromal depressive symptoms (Judd et al. 1998b; Maddux and Rapaport 2004).

Current epidemiological and clinical outcome data support the postulate that major depressive disorder is part of a fluid spectrum of depressive disorders. The presence of depressive symptoms—be they symptoms of subsyndromal depression or minor depression or residual symptoms after partially successful treatment—carries significant risks for psychosocial disability, increases the risk for chronicity, and is associated with greater medical comorbidity, greater health care utilization, greater risk for recurrence, and greater risk for suicide (Akiskal et al. 1997; Judd and Akiskal 2000; Rapaport et al. 2002; Wells et al. 1989). The results of preliminary clinical trials suggest that both minor depressive disorder and subsyndromal depressive disorder are responsive to treatment with either pharmacotherapy or focused brief psychotherapies (Maddux and Rapaport 2004; Rapaport et al. 2002). This paradigm shift has profound implications for how we conceptualize the goals for treatment of major depressive disorder. In the past, the goals of treatment were the acute amelioration of the most troublesome symptoms of major depressive disorder: a 50% response on an objective measure of the severity of depression was defined as a successful outcome. Now the goal of treatment for an episode of major depressive disorder is the complete eradication of depressive symptoms. Asymptomatic status is defined as the elimination of all signs and symptoms of depression and a return to normal functioning (Judd and Akiskal 2000; Judd et al. 1998b).

Another significant advance that has modified our conceptualization of major depressive disorder and

its treatment is the NIMH-funded Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study. This study is the largest and most authoritative investigation of the efficacy of an evidence-based approach to the acute treatment of major depressive disorder. Results from the STAR*D study (Trivedi et al. 2006d) indicate that only 28% of patients remit even with a systematic, ratings-guided initial trial with a selective serotonin reuptake inhibitor (SSRI). The majority of patients required a stepwise application of treatments with increasingly aggressive augmentation or treatment-switching strategies to attain remission (Rush et al. 2006b). At 6-month naturalistic follow-up, the patients who remitted earlier in their course of treatment and those with less resistant depression (i.e., those who remitted with level 1 or level 2 treatment [see study description in the "Acute Treatment" section]) were less likely to have relapsed at follow-up. This supports the idea that early successful treatment focused on remission gives the patient the best opportunity for long-term success. Further large-scale studies are needed to inform not only our continued understanding of acute therapy for depressive disorders but also our knowledge of what strategies are most effective during the continuation and maintenance phases of therapy.

The development and refinement of imaging techniques, preclinical models, molecular genetic techniques, and computational techniques are leading to a marked increase in our knowledge about the biological underpinnings of depressive disorders. At this time, we have not been able to link our phenotypic investigations of the course and prognosis of depressive disorders with specific biological processes; however, our knowledge of the neuroanatomical circuits that are abnormal in some patients with depressive disorders is rapidly expanding (Goldapple et al. 2004; Kennedy et al. 2001; Mayberg et al. 2000). This knowledge combined with fundamental advances in animal model development, molecular biology, and whole-genome scanning techniques in genetics will markedly alter our understanding of the biology of mood disorders in the future (Nemeroff and Vale 2005; Perlis 2007).

In summary, major depressive disorder is a chronic illness with symptoms that fluctuate over a continuum of severity. Even the mildest form of depression, subsyndromal depression, is associated with both psychosocial morbidity and a risk for developing major depressive disorder (Beekman et al. 1997; Fergusson et al. 2005; Fogel et al. 2006; Hermens et al. 2004; Judd et al. 1994; Rieckmann et al. 2006). The goal of treatment of all forms of depression needs to be the return to an asymptomatic state of the patient's prior "normal" functioning. Thus, the treatment of patients with major depressive disorder requires aggressive and varied therapies that may need to continue for years, if not indefinitely.

EPIDEMIOLOGY

Prevalence of Depressive Disorders

Major depressive disorder is one of the most common medical disorders affecting adults in the world (Lopez and Murray 1998). In the United States the lifetime prevalence of major depression for men is 9% and 17% for women (Hasin et al. 2005), while the lifetime prevalence of dysthymia is 4% for men and 8% for women (Kessler et al. 1994). The lifetime prevalence of minor depression is 10% for individuals between the ages of 15 and 54 years (Kessler et al. 1997). For persons 65 years and older, the 1-month point prevalence of minor depression is 13%, which is twice the prevalence of major depressive disorder for this age group (Judd and Akiskal 2002; McCusker et al. 2005). The lifetime prevalence for subsyndromal depression is 11.8% for the general population (Goldney et al. 2004; Judd et al. 1994).

Risk Factors for Depressive Disorders

Several risk factors seem to increase a person's vulnerability to developing a depressive disorder. The vulnerability factors for which the greatest preponderance of evidence exists suggesting that they might increase the risk include female sex, age, a family history of a mood disorder, a history of

trauma, and comorbid medical and psychiatric conditions.

A significant body of evidence indicates that the sex of an individual is an important risk factor for the development of depressive disorders. Prior to puberty the prevalence of depression is equal in boys and girls. However, beginning with puberty, women demonstrate a twofold increase in the prevalence of major depressive disorder (Weissman and Klerman 1977). This trend is seen across countries and ethnic groups (Weissman et al. 1996). The difference in prevalence rates between men and women is not easily understood. It has been postulated that the difference may in part be explained by the role of changes in levels of β-estradiol in the genesis of depression. Data suggest that there may be specific periods of the life cycle when a woman may be at greater risk of developing a mood disorder, such as during pregnancy and postpartum (Burt and Stein 2002; Joffe et al. 2002). It has also been speculated that this difference in prevalence rates may reflect the complex interplay between an intrinsic biological vulnerability, societal pressures, and a style of coping that more readily seeks help.

Age is another risk factor in the development of depressive disorders; the onset of major depressive disorder increases dramatically beginning in adolescence (12–16 years of age) and continuing through the age of about 44 years (Hasin et al. 2005). The mean age at onset has been reported to be 30 years, whereas the mean age at the start of treatment is 33.5 years of age, reflecting the amount of time depression often goes undiagnosed or untreated. In elderly populations, risk factors for depression are slightly different and include female sex, low socioeconomic status, bereavement, prior depression, medical comorbidity, disability, cognitive deterioration, and vascular disease (Helmer et al. 2004). The elderly are at risk for a "downward spiral" that can occur when disability or cognitive impairment leads to depressive symptoms, depressive symptoms increase disability, and so on. Depression in the elderly affects psychosocial function, health care utilization, quality of life, work productivity, risk for suicide, and medical compliance and outcome.

A family history of psychiatric illness is among the most profound risk factors for the development of an episode of major depressive disorder (Reinherz et al. 2003). No one gene has been clearly identified as a cause of major depression, and it may be concluded that depressive disorders are likely polygenetic in nature. This might further explain the heterogeneity of the disease and treatment response. New research has demonstrated that genetics coupled with environmental conditions may contribute to the development of depression. The work led by Caspi et al. (2003) and verified by others (Cervilla et al. 2007; Kendler et al. 2005) indicates that depressive responses to traumatic life events are modulated by genetic makeup. Individuals who carry two short alleles at the serotonin transporter (5-HTT) gene are more likely to develop depression after a stressful event than those with one or two long alleles. Other studies have found that genetic variants in the dopamine transporter (Elovainio et al. 2007) or enzymes responsible for polyamine catabolism (Sequeira et al. 2006) may be implicated as a risk factor for the development of depression.

Prolonged exposure to severe traumatic events in childhood has been linked to future depressive episodes. Trauma such as sexual abuse or the loss of a parent that occurs at a critical developmental period can result in permanent alteration of the hypothalamic-pituitary-adrenal (HPA) axis. It is recognized that individuals with depression, particularly those exposed to early trauma, have altered stress responses (Gillespie and Nemeroff 2005; Heim et al. 2000; Nemeroff and Vale 2005). Some individuals with major depressive disorder have altered HPA axis activity with elevated circulating levels of cortisol, hypersecretion of corticotropin-releasing hormone, and adrenal hypertrophy, which normalize after resolution of depressive symptoms (Nemeroff and Vale 2005).

Other clinical and demographic variables have been linked to an increased risk of developing depressive disorders. These include stressful life events such as the death of a loved one, divorce, or job loss. Certain personality characteristics also may predispose an individual to develop a mood disorder. Individuals who score higher on measures of neuroticism, interpersonal dependency, or external locus of control may be vulnerable to stressful life events precipitating a major depressive

episode (Hirschfeld et al. 1983; Paykel et al. 1996). Investigations suggesting that certain cultural groups may be at increased risk of a mood disorder (Native Americans) and that other cultural groups may have greater inherent resilience (Asian and Hispanic groups) are an area of renewed interest (Hasin et al. 2005). Further investigation of the role that intrinsic cultural differences may play, not only in the presentation of major depressive disorder but also in the protection against depressive symptoms, is warranted (Harris 2004).

Many medical illnesses are comorbid with major depressive disorder (Table 53–1). Cancer, acquired immunodeficiency syndrome, respiratory disease, cardiovascular disease, Parkinson's disease, and stroke are associated with an increased risk for depression. An interesting bidirectional relationship exists between depression and cardiovascular disease. For example, depression is a risk factor for a future cerebrovascular accident, and stroke is a well-documented risk factor for depression. Although there are little data on prevalence rates, an acute myocardial infarction is a risk factor for depression. Some studies suggest that depression is common among cardiac patients, with 40%–50% of cardiac patients having mild, moderate, or major depressive symptoms and women being more likely to be depressed than men (Drago et al. 2007). The presence of moderate or major depression following myocardial infarction increases the risk for death by 3.5 times (Glassman and Shapiro 1998). Depression is also associated with rehospitalization and mortality in patients with heart failure.

TABLE 53–1. Medical conditions often comorbid with major depressive disorder

Infectious	Metabolic	Neurological	General medical
Encephalitis	Addison's disease	Brain tumor	Alcohol or sedative withdrawal
Hepatitis	Cushing's disease	Dementia, cortical	Arthritis
HIV/AIDS	Diabetes	Dementia, subcortical	Cancer
Influenza	Hyponatremia	Huntington's disease	Cardiovascular disease
Meningitis	Nutritional deficiencies	Migraine headaches	Chronic pain syndromes
Mononucleosis	Pituitary dysfunction	Multiple sclerosis	Cocaine or stimulant withdrawal
Pneumonia	Renal disease	Parkinson's disease	Connective tissue diseases
Postviral syndrome	Thyroid disease	Poststroke syndrome	Fibromyalgia
Syphilis		Seizure disorders	Heavy metal poisoning
Tuberculosis		Traumatic brain injury	Irritable bowel syndrome
Urinary tract infection			Liver failure
			Menopause
			Myocardial infarction
			Premenstrual syndrome
			Pulmonary disease
			Selenium toxicity
			Sleep disturbance

Note. AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency virus.

Major depressive disorder is highly comorbid with other psychiatric disorders such as anxiety, dementia, schizophrenia, and substance abuse. In primary care settings, more than 75% of patients with diagnosed depression also present with an anxiety disorder (Olfson et al. 1997). Patients with depression and anxiety have more chronic and severe illness, greater occupational and psychosocial

impairment, and, when the comorbidity is unrecognized, a greater rate of psychiatric hospitalization and suicide attempts (Hirschfeld 2001). Fifty percent of schizophrenic patients have comorbid depression. When present with schizophrenia, depression is an additional risk factor for suicide and decreased social and performance status (Ginsberg et al. 2005). The rate of major depressive disorder in Alzheimer's disease patients is between 20% and 40%. Diagnosing depression in Alzheimer's disease may be complicated by the overlap between symptoms of dementia and those of depression: loss of motivation, social withdrawal, isolation, and apathy are common to both disorders. Persons with dementia may have difficulty verbalizing subjective feelings such as sadness or hopelessness. Therefore, observable behavioral signs and symptoms such as irritability, social withdrawal, worsened functional impairment, and agitation may be more reliable indicators of the presence of a mood disorder in patients with Alzheimer's disease. There seems to be a complex relationship between depression and dementia: the presence of depression may be a harbinger of dementia, and dementia seems to be a risk factor for depression (Potter and Steffens 2007). Substance abuse is also highly comorbid with depressive disorders. Estimates of the prevalence of depressive disorders in patients with alcohol dependence is 15%–67%; for patients with cocaine addiction the prevalence is 33%–53%, and for patients with opiate dependence the lifetime rate of affective disorders ranges from 16% to 75% (Nunes 2003). Symptoms of substance withdrawal (cocaine, methamphetamine, alcohol) do overlap with symptoms of depression, but the type and severity tend to be distinctly different (Rapaport et al. 1993).

In summary, the exploration of factors that influence vulnerability and resilience has been complicated by the heterogeneity of depressive disorders. Despite this obstacle, it is clear that certain moderating factors have been identified that increase the risk of developing a depressive disorder. These include female sex, aging, family history, childhood trauma, certain personality styles, stressful life events, and presence of other psychiatric and medical illnesses.

Disability and Costs Associated With Depressive Illnesses

Major depressive disorder is associated with significant disease burden, exceeding that of cerebrovascular diseases and cancer. It is the leading cause of years lived with disability worldwide for young adults (Lopez et al. 2006). Psychosocial disability progresses along a gradient parallel to the increasing severity of depressive symptoms (Judd et al. 2000; Kessler et al. 1997). People with subsyndromal depressive symptoms and depressive disorder have higher disability ratings for social and role functioning than patients with hypertension, diabetes, arthritis, gastrointestinal problems, or back problems (Rapaport et al. 2002). Depressed persons rate themselves as having worse health and spend more days in bed than patients with many other chronic medical conditions including arthritis, diabetes, and lung disease (Wells et al. 1989). Even patients with minimal symptoms or subsyndromal depression have functional impairment more akin to that seen in patients with major depression than in nondepressed control subjects (Beekman et al. 2002). Thus, patients with depressive disorders have decreased income, productivity, physical functioning, and health status and more days spent in bed than control populations (Judd et al. 1996; Maddux and Rapaport 2004).

The costs associated with major depressive disorder are staggering. For individuals 18–65 years of age, 85% of the cost of depressive disorders is due to lost productivity (Smit et al. 2006). It is estimated that depressive disorders cost employers in the United States $44 billion in productivity annually. Twenty percent of this financial burden is due to absenteeism, with 80% of this loss due to *presenteeism*; that is, a worker is well enough to come to work but unable to perform the job efficiently (Stewart et al. 2003). Thus, although individuals who are mildly depressed may appear to be functional, subtle impairments in abilities have a significant impact on productivity.

Depressive disorders are also prevalent and incur significant societal costs in the elderly (Cuijpers et al. 2004; Horowitz et al. 2005). In contradistinction to the costs in younger adults, the costs associated with major depressive disorder and other forms of depression in the elderly are primarily

driven by increased health care utilization, medical disease burden, and mortality.

The greatest "cost" associated with depressive disorders is the increased likelihood that an individual suffering from a depressive disorder will commit suicide. According to the Centers for Disease Control and Prevention, suicide is the eleventh leading cause of death in the United States: approximately 32,000 known suicides were identified in the 2005 census. In that year the overall suicide rate was almost double the homicide rate in the United States (11.05 per 100,000 vs. 5.9 per 100,000). Suicide is the second leading cause of death for individuals between the ages of 25 and 34 years and the third leading cause of death for young people between the ages of 15 and 24 years. Eighty percent of people who commit suicide are male. Suicide is more common in white than Hispanic or black individuals. Statistical risk factors for suicide include being male, being white, being single, having been hospitalized for a suicide attempt or having any history of a previous attempt, having a family history of suicide, and abusing substances. Women are more likely to attempt suicide, whereas men are more likely to complete it. In fact, longitudinal 40-year data from F. Angst et al. (2002) suggested that the 17.7% of the Zurich community cohort of people with a diagnosis of major depressive disorder committed suicide.

The elderly constitute a special at-risk group for successful completion of suicide. People older than 65 years constitute only 13% of the population and yet are responsible for 18% of all suicides: this is the highest suicide rate for any age group. Risk factors for suicide among older individuals are slightly different than the factors among younger individuals; for older individuals they include social isolation, physical illness, divorced or widowed status, and male sex (U.S. Department of Health and Human Services 2001). Older individuals who attempt suicide usually employ more lethal means (guns, drug overdoses) than younger individuals do.

It is clear that early identification and vigorous treatment are essential to decrease the likelihood that an individual with a depressive disorder who is suicidal will take his or her life (Clayton and Auster 2008). Despite recent guidance from the U.S. Food and Drug Administration (FDA) suggesting that suicidal thoughts and behavior among individuals younger than 25 years may increase during the first 10 days after starting an antidepressant, and despite a recent report based on the STAR*D database that found an association between two ionotropic glutamate receptor genes (*GRIA3* and *GRIK2*) and an increased risk of SSRI-induced suicidal thoughts, the vast majority of data suggest that antidepressant medication decreases suicidal thoughts and lowers rates of suicide completion (R. D. Gibbons et al. 2005; Henriksson and Isacsson 2006; Laje et al. 2007; Rich and Isacsson 1997; Søndergård et al. 2006). These observations are supported by the longitudinal work of J. Angst et al. (2005), who found that treatment with antidepressants, lithium, and clozapine reduced the number of suicides in their cohort. They observed that long-term treatment, particularly combined treatment, was associated with reduced overall mortality over 40-year follow-up. Taken as a whole, these data suggest that suicidal ideation with intent and planning must be considered a medical emergency that merits the same type of diligent care that a physician would give to other emergent conditions like a myocardial infarction.

DEFINITION OF DEPRESSIVE ILLNESS

Beginning with DSM-III (American Psychiatric Association 1980), American psychiatry made the transition to descriptive nosology. The hallmarks of DSM-IV (American Psychiatric Association 1994) nosology for depressive illness are the requirement that a constellation of signs or symptoms be present for a minimum length of time and that they induce some type of measurable functional impairment. For the diagnosis of *major depressive episode,* an individual must have experienced, over a single 2-week period, one of two "gatekeeper" symptoms—feeling sad/"blue" or having anhedonia—plus four additional symptoms. These symptoms must cause substantial functional impairment or disability, cannot be due a concomitant medical or substance use disorder, and must persist every day for a significant portion of the day. DSM-IV-TR (American Psychiatric Association

2000a) criteria for major depressive episode are presented in Table 53–2.

TABLE 53–2. DSM-IV-TR criteria for major depressive episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly due to a general medical condition, or mood-incongruent delusions or hallucinations.

(1) depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). Note: In children and adolescents, can be irritable mood.

(2) markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others)

(3) significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. Note: In children, consider failure to make expected weight gains.

(4) insomnia or hypersomnia nearly every day

(5) psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)

(6) fatigue or loss of energy nearly every day

(7) feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)

(8) diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)

(9) recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide

B. The symptoms do not meet criteria for a mixed episode.

C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

D. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

E. The symptoms are not better accounted for by bereavement (i.e., after the loss of a loved one, the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation).

DSM-IV-TR allows the clinician to categorize the severity of the depressive disorder as *mild* (symptoms barely meet the threshold for diagnosing the disorder and are not associated with significant impairment), *moderate* (symptoms and functional impairment are somewhere between mild and severe), or *severe* (several symptoms in excess of those required to make the diagnosis are present, and symptoms markedly impair the individual's functioning). The current nosology classifies psychotic depression as *major depressive disorder, severe, with psychotic features,* rather than as a distinct entity. DSM-IV-TR also provides specifiers to characterize the current depressive episode, the two most significant being "with melancholic features" and "with atypical features." DSM-IV-TR criteria for the melancholic features specifier and for dysthymic disorder are presented in Tables 53–3 and 53–4, respectively.

TABLE 53–3. DSM-IV-TR criteria for melancholic features specifier

Specify if:

With melancholic features (can be applied to the current or most recent major depressive episode in major depressive disorder and to a major depressive episode in bipolar I or bipolar II disorder only if it is the most recent type of mood episode)

A. Either of the following, occurring during the most severe period of the current episode:

(1) loss of pleasure in all, or almost all, activities

(2) lack of reactivity to usually pleasurable stimuli (does not feel much better, even temporarily, when something good happens)

B. Three (or more) of the following:

(1) distinct quality of depressed mood (i.e., the depressed mood is experienced as distinctly different from the kind of feeling experienced after the death of a loved one)

(2) depression regularly worse in the morning

(3) early morning awakening (at least 2 hours before usual time of awakening)

(4) marked psychomotor retardation or agitation

(5) significant anorexia or weight loss

(6) excessive or inappropriate guilt

TABLE 53–4. DSM-IV-TR criteria for 300.4 dysthymic disorder

A. Depressed mood for most of the day, for more days than not, as indicated either by subjective account or observation by others, for at least 2 years. Note: In children and adolescents, mood can be irritable and duration must be at least 1 year.

B. Presence, while depressed, of two (or more) of the following:

(1) poor appetite or overeating

(2) insomnia or hypersomnia

(3) low energy or fatigue

(4) low self-esteem

(5) poor concentration or difficulty making decisions

(6) feelings of hopelessness

C. During the 2-year period (1 year for children or adolescents) of the disturbance, the person has never been without the symptoms in criteria A and B for more than 2 months at a time.

D. No major depressive episode has been present during the first 2 years of the disturbance (1 year for children and adolescents); i.e., the disturbance is not better accounted for by chronic major depressive disorder, or major depressive disorder, in partial remission.

Note: There may have been a previous major depressive episode provided there was a full remission (no significant signs or symptoms for 2 months) before development of the dysthymic disorder. In addition, after the initial 2 years (1 year in children or adolescents) of dysthymic disorder, there may be superimposed episodes of major depressive disorder, in which case both diagnoses may be given when the criteria are met for a major depressive episode.

E. There has never been a manic episode, a mixed episode, or a hypomanic episode, and criteria have never been met for cyclothymic disorder.

F. The disturbance does not occur exclusively during the course of a chronic psychotic disorder, such as schizophrenia or delusional disorder.

G. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).

H. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:

Early onset: if onset is before age 21 years

Late onset: if onset is age 21 years or older

Specify (for most recent 2 years of dysthymic disorder):

With atypical features

DSM-IV-TR provides two other major categorizations for unipolar depressive disorders: *dysthymic disorder* and *depressive disorder not otherwise specified.* (The cardinal features of dysthymic disorder are presented in Table 53–4.) In order to be classified as having dysthymic disorder, an individual may not meet the threshold criteria for major depressive disorder during the first 2 years of illness and cannot be better characterized as having *major depressive disorder, chronic,* or *major depressive disorder, in partial remission.* Dysthymic disorder is thought to have an early and insidious onset. Most patients who are seen in clinical settings seek treatment because of a major depressive disorder that has become superimposed on dysthymia. These cases of *double depression* tend to be challenging to treat and have a worse prognosis than uncomplicated major depression.

The category *depressive disorder not otherwise specified* has been used as a catchall for the presence of signs and symptoms of depression that do not meet criteria for major depressive disorder, dysthymia, or one of the adjustment disorders. Minor depressive disorder and subsyndromal depressive disorder fall within the rubric of depressive disorder not otherwise specified in DSM-IV-TR. More recent work has demonstrated that minor depressive disorder is associated with significant disability, morbidity, and impairment (Howland et al. 2008; Judd and Akiskal 2000; Judd et al. 1994; Rapaport and Judd 1998; Rapaport et al. 2002). In contradistinction to major depressive disorder, minor depressive disorder is characterized mostly by affective and cognitive symptoms such as sadness, loss of pleasure/enjoyment, irritable mood, anxious mood, pessimism, difficulty concentrating, lack of involvement, and fatigue. This constellation of symptoms has been demonstrated to be stable and persistent in individuals with minor depression (Rapaport et al. 2002). The research criteria for minor depressive disorder in the appendix of DSM-IV-TR exclude individuals who have had a prior episode of major depressive disorder. However, research suggests that this is unnecessarily restrictive; subjects with and without a prior history of major depressive disorder have identical demographic and clinical presentations, severity of illness, and acute treatment response (Howland et al. 2008; Judd et al. 2004; Rapaport et al. 2002).

A number of different definitions of subsyndromal depressive disorder have been discussed in the literature. For many investigators, subsyndromal depressive disorder is thought to be equivalent to minor depressive disorder. However, Judd et al. (1994) suggested that subsyndromal depressive disorder be defined as the presence of any of two or more associated symptoms of depression: problems with sleep, appetite, concentration, or suicidal thinking without the presence of sadness or anhedonia. Although there is no consensus about the diagnosis of subsyndromal depression at this time, the presence of signs and symptoms associated with depression has negative prognostic value.

Such individuals are at greater risk of developing an episode of minor or major depressive disorder within the next year (Judd et al. 1994, 1997).

In conclusion, the definitions of the syndromes that constitute the spectrum of unipolar mood disorders will continue to evolve with our understanding of the neurobiology of what we call mood disorders.

NEUROBIOLOGY OF DEPRESSION

Depressive disorders have many features that clearly indicate a complex neurobiological component to the disease state. The discovery in the 1950s of antidepressant pharmacological therapies provided the initial evidence of an underlying biochemical alteration in depressed patients. Studies in genomics and imaging and the identification of neural pathways involved have advanced our knowledge. As a result, several complementary but distinct lines of investigation into the neurobiology of depression have begun to take hold.

Depression has for many years been predominantly hypothesized to be marked by a depletion of monoamine neurotransmitters, specifically norepinephrine, serotonin, and dopamine. The involvement of monoamines in mood alterations was first documented in the 1950s with the observation that individuals treated with high doses of reserpine, an antihypertensive agent that depletes the brain of monoamines, developed depression (Freis 1954). Later studies of monoamine depletion were developed to investigate the direct effects of monoamines on mood. Because monoamines are synthesized from essential amino acid precursors tryptophan (for serotonin) and tyrosine (for norepinephrine and dopamine), a transient depletion can be achieved by ingesting a tryptophan-free or tyrosine-free amino acid mixture. In healthy individuals, depressed mood has been noted after tryptophan or tyrosine depletion in some studies, although more marked results are found in subjects with a family history of mood disorders or in drug-free subjects in remission from depression (Ruhe et al. 2007). Although depletion studies have never induced levels of clinical depression in healthy individuals or increased depressive symptoms in clinically ill patients not taking medication, what has been intriguing is that subjects with major depression who responded to SSRIs relapsed after serotonin depletion (Delgado et al. 1990). These results suggest that patients who are clinically ill with major depression have deficits in brain monoamine concentrations and that these deficits play a modulatory role with other systems that have a more direct role in the symptoms of depression.

As our understanding has grown about the mechanism of action of antidepressant therapies, more attention has been given to the neurotransmitter systems involving glutamate and γ-aminobutyric acid (GABA). Evidence for the role of these neurotransmitter systems in depression comes from studies of therapies that have been shown to target the *N*-methyl-D-aspartate (NMDA) class of glutamate receptors, specifically lamotrigine, ketamine, and amantadine (Pittenger et al. 2007), and anticonvulsant therapies, which have a GABAergic route of action. Studies have demonstrated alterations of these systems in subjects with depression. One postmortem gene expression study demonstrated that the brains of suicide victims suffering from major depression had downregulation of the spermidine/spermine N1-acetyltransferase (SSAT) gene, which was subsequently linked to the presence of an allelic variant (Sequeira et al. 2006). SSAT is the rate-limiting enzyme for the catabolism of polyamines, which in turn regulate the NMDA receptors. Furthermore, a meta-analysis of the body of studies performed revealed that cerebrospinal fluid levels of GABA in subjects with depression are significantly lower than levels in nondepressed control subjects (Petty et al. 1993).

Depression is also marked by dysregulation of other important systems. External stressful stimuli are known to be a major risk factor for a depressive episode, and depressed individuals are often characterized with altered biological responses to stress. This is likely due to dysregulation and overstimulation of the HPA axis (Gertsik and Poland 2004; Holsboer 1995). Early studies (Brown and Shuey 1980; Carroll 1982; Coppen et al. 1983) found that in a large percentage of unmedicated

individuals with depression, secretion of the stress hormone cortisol is not suppressed after dexamethasone administration, a condition known as *dexamethasone nonsuppression.* Dexamethasone is a synthetic glucocorticoid and acts at the level of the anterior pituitary corticotrophs to reduce the secretion of adrenocorticotropic hormone (ACTH), which in turn decreases the production of cortisol in the adrenal cortex. Dexamethasone nonsuppression therefore indicates impairments in the feedback mechanisms of the HPA axis. Correspondingly, elevated levels of circulating cortisol have been reported in subjects with depression (J. L. Gibbons and McHugh 1962; Rubin et al. 1987). This impairment of HPA axis regulation has been traced upstream to dysregulation of corticotropin-releasing hormone (CRH), a hypothalamic hormone that controls the release of ACTH (Holsboer 2000). Depressed individuals have higher CRH neuronal activity (Raadsheer et al. 1994) and display a blunted ACTH and cortisol response to infusion of synthetic CRH (Gispen-de Wied et al. 1993; Gold et al. 1986). This global hyperactivity of the stress response in depressed individuals has been demonstrated to be a characteristic of the current depressed state, because the remission of clinical symptoms induces a normalization of responses to dexamethasone or CRH along with normalization of plasma cortisol levels (Amsterdam et al. 1988; Arana et al. 1985; Sachar et al. 1970). Dysregulation of the HPA axis activity and higher rates of depression are more prominent in individuals exposed to childhood trauma or abuse (Bremne and Vermetten 2001), suggesting that hyperactivity of the HPA axis during critical periods of brain development leads to higher rates of depression later in life.

This cascade of alterations in the HPA axis, and subsequent increase in glucocorticoids, is thought to be responsible for the structural and functional changes seen in the limbic structures of depressed individuals. In vivo magnetic resonance imaging studies demonstrate hippocampal shrinkage in depressed patients relative to healthy control subjects (Campbell et al. 2004; Videbech and Ravnkilde 2004). Although the exact mechanism of this loss of hippocampal volume is unknown, it is presumably through cell death, cell atrophy, and/or reduction in neurogenesis. Successful antidepressant therapy has been shown to increase cellular proliferation (Duman 2004; Warner-Schmidt and Duman 2006), and chronic stress induces the converse, giving further credence to the neurobiological component of depression.

Taken together, these observed alterations in monoamines and other neurotransmitters, in the HPA axis function, and in neuronal plasticity can be conceptualized as a state of depressive illnesses rather than a trait of the illnesses. Given that successful clinical therapies often reverse these trends, one has to ask, What is the underlying cause? It is clear that a familial predisposition to depression is present, lending support to the idea of a genetic component to depression. Ongoing research has failed to pinpoint a specific genetic anomaly, which is likely due to the heterogeneity of the disorder and the additive role that environmental factors play in triggering depressive episodes in individuals who may be genetically predisposed to depression. However, with the advent of high-throughput technology, such as whole-genome sequencing and single nucleotide polymorphism detection, specific genetic trends have been demonstrated.

Some very positive studies point to polymorphisms of the *5-HTT* gene (Caspi et al. 2003; Kendler et al. 2005) that may modulate the sensitivity of individuals to stressful life events. Additional work has implicated allelic polymorphisms in glucocorticoid receptors (Binder et al. 2004; Brouwer et al. 2006; van Rossum et al. 2006) and CRH receptors (Liu et al. 2007; Papiol et al. 2007). Most interesting has been the discovery that there exist subpopulations of depressed individuals with genetic anomalies in the *5-HTT* gene who have a higher risk of developing adverse side effects to SSRI treatment than individuals without those anomalies (Hu et al. 2007; Smits et al. 2007a). A study was conducted to determine whether genetic prescreening for a variant in the *5-HTT* gene to identify which class of antidepressants would be best suited for each subject's course of treatment would lead to better treatment outcomes (Smits et al. 2007b). Positive results were minor, however, and the costs involved suggest that the gains made were unsubstantial. One clear genetic variation that has been

demonstrated as clinically valuable is alteration in the gene for the cytochrome P450 enzyme CYP2D6, a liver enzyme involved in drug metabolism. Individuals may have normal, intermediate, or poor metabolism rates depending on whether they carry no alleles, one allele, or two alleles. This trait has been seized on as a potential aid in properly dosing patients, and the FDA has approved use of a test to aid physicians in genetic testing (Roche Pharmaceuticals 2008).

Other studies have begun to examine the contribution of the immune system and cytokines in major depressive disorder, suggesting a new avenue for therapeutic alternatives. Cytokines are a heterogeneous group of signaling and regulatory molecules produced by immunocompetent cells, and generally are categorized as proinflammatory or anti-inflammatory. The proinflammatory cytokines interferon alfa and interferon gamma have potent antiviral and immunomodulatory properties and are used to treat various forms of cancer and hepatitis C (Adams et al. 1984; Borgstrom et al. 1982; Meyers 1999). These cytokine therapies have been noted to be accompanied by depressed behavioral effects that can be significantly reduced by pretreatment with paroxetine (Capuron et al. 2002; Musselman et al. 2001), thus supporting the cytokine theory of depression. Furthermore, individuals with depressive disorders have higher plasma concentrations of the proinflammatory cytokines interleukin 1 (IL-1) and interleukin 6 (IL-6) than do nondepressed individuals, and concentrations correlate with the severity of depressive symptoms (Maes 1995, 1999). Some studies have demonstrated that the immune system is in an activated state in subjects with depressive disorders (Kling et al. 2007; Maes et al. 1995; Schiepers et al. 2005; Sluzewska et al. 1996). Although the precise role that cytokines play in depression is difficult to elucidate, continued research in this direction is warranted.

As presented in greater detail in other chapters of this book (see Chapter 45, "Neurobiology of Mood Disorders"), it is clear that our understanding of the biological underpinnings of depressive disorders is rapidly increasing. In the future the combination of advances in molecular medicine, imaging, and data analysis will begin to clarify the relationship between what currently appear to be disparate biological findings.

EVALUATION OF DEPRESSION

Context

The setting of the psychiatric assessment is important in that it provides a context that defines the focus of the encounter and therefore the content of the examination. For example, the assessment of the depressed patient in the emergency room is very different from the assessment of the depressed patient in the office, and that is very different from the assessment within a general hospital setting. The assessment of a depressed person in the emergency room focuses on a rapid, yet thoughtful, determination of safety and appropriate disposition—that is, does this person require hospitalization or is treatment in a less restrictive environment more appropriate? To expedite the determination of disposition in the emergency room, the evaluation focuses on issues of safety, suicidal thinking, future orientation, stability of social supports, housing, and recent drug and alcohol use. This assessment should also include a review of recent life events and potential precipitating stressors. Collateral information from family, friends, and outside physicians is helpful in determining the appropriate level of care.

In the office setting, it is possible to carry out a more traditional and complete initial examination. This includes a detailed review of the patient's signs and symptoms of depression, any comorbid medical or psychiatric disorders, and the patient's psychiatric history. A family history of psychiatric illness is very important. The focus of the initial evaluation is on establishing rapport, determining a working diagnosis, and developing an initial treatment plan.

In contrast, when a psychiatrist is acting as a consultant in a general hospital setting, the assessment has a different focus. Because either the illness itself or a treatment intervention may have provoked

the episode requiring hospitalization, the consultant needs to carefully review the current medical chart. The stress of the hospitalization, bereavement, delirium, or a head injury may mimic a depressive disorder in an individual hospitalized in an acute care setting. Somatic symptoms such as pain, constipation, insomnia, and nausea frequently stimulate angry behavior or exacerbate a sense of helplessness in a patient. The amelioration of such somatic concerns may decrease the intensity of depressive symptoms in the hospital setting. Thus, the goals of the consultant in a general hospital setting are to determine a working diagnosis and intervention plan, to communicate this to the primary care team, to facilitate its implementation, and to establish a plan for follow-up after discharge.

Initial Evaluation and Differential Diagnosis

Although all psychiatrists have been trained in the appropriate approach to initial examination and differential diagnosis, unfortunately many times patients are misdiagnosed because components of the diagnostic assessment have been inadvertently omitted. It is important to remember that a complete initial diagnostic assessment should include not only the history of the present illness but also a complete assessment of current and past comorbid psychiatric conditions, a family medical and psychiatric history, and a social and developmental history. Frequently, busy practitioners forget to ask about early childhood trauma or sexual trauma. Performing a formal mental status examination may be particularly important if one is assessing either an older person with a depressive disorder or someone with significant medical comorbidities.

One needs to either contact the primary care physician or consider performing a medical history and a physical examination for patients with a new onset of major depressive disorder. Many medical conditions, medications, and substances (alcohol, benzodiazepines, barbiturates) can cause depressive symptoms, as shown in Tables 53–1 and 53–5.

TABLE 53–5. Medications that may cause depression

Acyclovir	Clonidine	Metoclopramide
Alcohol	Cocaine (withdrawal)	Metrizamide
Amantadine	Contraceptives	Metronidazole
α methyldopa	Corticosteroids	NSAIDs
Amphetamines (withdrawal)	Cycloserine	Opiates
Anabolic steroids	Dapsone	Pentazocine
Anticonvulsants	Digitalis	Pergolide
Antihistamines	Disopyramide	Phenylpropanolamine
Antineoplastic agents	Disulfiram	Physostigmine
Antipsychotic medications	Estrogens	Prazosin
Baclofen	Ethambutol	Progestins, implanted
Barbiturates	Fluoroquinolone antibiotics	Reserpine
Benzodiazepines	Guanethidine	Statins
β-adrenergic blockers	Interferon alfa	Sulfonamides
Bromocriptine	Isotretinoin	Thiazide diuretics
Calcium channel blockers	Levodopa	
Cimetidine	Mefloquine	

Note. NSAIDs = nonsteroidal anti-inflammatory drugs.

Rating Scales

One of the greatest challenges psychiatry and psychology have faced is quantifying the impact of psychiatric illness and therapies on a patient's life. Most practitioners do not establish baseline levels of symptom severity and do not systematically measure the changes in symptoms caused by their interventions. Some have worried that introducing scales to systematically assess symptom severity would contaminate the therapeutic process; however, this postulate has fallen out of favor. As the biology of depressive disorders is beginning to be elucidated and depressive disorders are being recognized as syndromes related to brain dysfunction, it is imperative for practitioners to employ a more rigorous approach to assessment and treatment. With "pay for performance" standards coming to psychiatry in the near future, employing standardized assessments will place the practitioner ahead of the curve in demonstrating the effectiveness of his or her treatment interventions.

Objective measurement of signs and symptoms of depressive disorders facilitates a more rational approach to treatment. These assessments provide accurate delineation of the severity of baseline signs and symptoms of depression. Thus, as was done in the STAR*D study, the clinician can use follow-up assessments to guide therapeutic decisions. Ratings also can be used as a tool to engage patients in their therapy and as an ongoing component of psychoeducation about depressive disorders.

The most commonly employed ratings (Table 53–6) evaluate the severity and frequency of specific symptoms associated with depression. These items' scores are usually summed into a composite score that represents the overall severity of the syndrome. The rating scales can be divided into two large groups: clinician-rated scales and self-report scales. For many years the field of psychiatry has placed greater value on clinician-rated scales. Proponents of clinician-rated scales suggest that they are more objective because the clinician is an unbiased observer, judging the severity and frequency of the symptoms (Carroll et al. 1973). Some favor clinician-rated measures because they allow the interviewer an opportunity to ask the patient follow-up questions and elicit sufficient data to ensure the accuracy of an answer. However, such ratings are highly dependent on the skill of the interviewer and the interviewer's fidelity to the intent and structure of the instrument. Proponents of patient-rated measures argue that a patient can provide a unique and valuable perspective to the assessment of his or her illness. Critics have raised legitimate concerns about self-reporting bias (Carroll et al. 1973); such bias could take the form of symptom minimization or symptom exaggeration. Furthermore, the presence of a negative cognitive schema might lead patients to minimize the extent of improvement that occurs early in therapy. Yet self-report assessments can be an important tool to enhance self-monitoring as the patient begins to "buy in" to therapy and adherence.

Quality of Life in Depression Scale

Clinician-Rated Scales

Three clinician-rated scales are commonly used to assess the severity of major depressive disorder: the Hamilton Rating Scale for Depression (Ham-D), the Montgomery-Åsberg Depression Rating Scale (MADRS), and the Inventory of Depressive Symptoms (IDS). These are described below:

1. The initial Ham-D was a 17-item scale developed by Max Hamilton in the United Kingdom while he worked with inpatients with primarily endogenous major depressive disorder (Hamilton 1960, 1967). When the scale was first published, it was suggested that the interview would usually require 45–60 minutes to perform (Hamilton 1960). This scale became a mainstay of depression research, and a variety of iterations emerged: 21-, 24-, 25-, 28-, and 31-item forms of the Ham-D (Ham-D-21, Ham-D-24, etc.). Shorter forms of the original Ham-D have also been proposed that are thought to measure the "core features" of depression, but these have not been widely accepted by clinicians. Other attempts to refine the Ham-D have included the development of structured interviews. The most popularly accepted form is the Structured Interview Guide for the Ham-D (SIGH-D; Williams 1988), but that has recently been supplanted by the GRID-Ham-D, which systematically measures the severity and frequency of symptoms (Tabuse et al. 2007). Thus, the Ham-D is a commonly used clinician-rated scale with multiple refinements that has been frequently employed in research settings.
2. The MADRS (Montgomery and Åsberg 1979) was developed to be sensitive to the potential benefits of pharmacological interventions. It is shorter than the standard Ham-D-17 and does not contain as many items measuring somatic concerns or anxiety. Items are rated from 0 to 6, with two items not having the benefit of a specific series of descriptors to anchor them to the rest of the scale. This is a reliable and well-validated scale (Khan et al. 2004).
3. The IDS has both clinician-rated and self-report forms. The clinician-rated form has 30 items that are rated 0–3. This scale includes cognitive signs and symptoms of depression as well as the DSM-IV symptoms (Rush et al. 1986; Trivedi et al. 2004). It has been well validated. The IDS clinician-rated scale also comes in an abbreviated form, the Quick Inventory of Depressive Symptoms (Rush et al. 2003). This version rates all of the DSM-IV signs and symptoms of depression from 0 to 3. It is well validated and was one of the primary outcome measures in the STAR*D study (Rush et al. 2006a; Trivedi et al. 2004).

Self-Report Scales

A wide array of self-report measures are available for patients and clinicians to consider:

1. One of the first measures developed was the Zung Self-Rating Depression Scale (Zung 1965). This 20-item scale, with ratings from 1 to 4, measures the severity of depressive symptoms. As is the case with the Ham-D, the scale was developed prior to the advent of DSM-III, so some features of the scale are not as closely aligned with our current nosology as the more recently developed self-report measures (Guy 1976).
2. A second self-rating scale commonly employed, particularly in psychology, is the Beck Depression Inventory

(BDI; A. T. Beck and Beamesderfer 1974). The BDI is a byproduct of A. T. Beck's descriptive, theoretical, and treatment work investigating cognitions and depression. It is a well-validated and commonly employed measure that focuses primarily on the more cognitive aspects of depression.

3. Another instrument, which has been gaining greater acceptance as a patient-rated measurement of major depressive disorder, is the Public Health Questionnaire–9. This questionnaire consists of the first nine items of the larger Public Health Questionnaire that was developed as an assessment tool for studying primary care patients (Kroenke et al. 2001). The nine symptoms are 1) depressed mood, 2) anhedonia, 3) appetite change, 4) sleep disturbance, 5) psychomotor change, 6) loss of energy, 7) feelings of worthlessness/guilt, 8) diminished concentration, and 9) suicide.

   Each item is scaled from absent (a score of 0) to present nearly every day (a score of 3). This instrument is well validated and has been used to longitudinally follow the course of illness because it is possible to assess the presence or absence of symptoms (Cannon et al. 2007; Kroenke et al. 2001). However, this instrument does not directly measure the intensity of symptoms.
4. A fourth patient-rated measure that is widely used is the Quick Inventory of Depressive Symptoms–Self-Report (QIDS-SR; Rush et al. 2003). This instrument correlates highly with the clinician-rated version. It includes assessments of intensity and frequency and covers all the cardinal signs and symptoms of major depressive disorder outlined in DSM-IV. This measure is easy for both clinicians and patients to use (Trivedi et al. 2004).

Self-report measures of work and functioning

If one is to reconceptualize major depressive disorder, symptoms are only part of the syndrome. Major depressive disorder impacts the individual's physical health, ability to function, interactions with significant others, interactions with family members, and quality of life. Thus, it is important to quantify not only the severity of symptoms but also the impact of the syndrome on other aspects of the patient's life. There are three readily available self-report measures of work and functioning that the clinician can ask the patient to complete:

1. One of the best-validated instruments is the Endicott Work Productivity Scale (Endicott and Nee 1997). Although this has the advantage of being well validated and complete, it has the disadvantage of being relatively time-consuming for the patient to use.
2. A second scale that has been validated, and that is very easy to use, is the Work and Social Adjustment Scale (Mundt et al. 2002). It consists of five Likert scales that measure an individual's perception of work and social functioning.
3. The Sheehan Disability Scale (Leon et al. 1992) is another simple and widely accepted approach to assessing disability. This 3-item Likert scale measures dysfunction at work, in social settings, and with family members. It is very easy to perform, is reliable, and has high patient acceptance.

Measurements of Quality of Life

Measurement of quality of life has been increasingly recognized as an important component for the treatment of psychiatric illnesses. There are several widely used instruments that measure aspects of quality of life, as described below:

1. The most widely accepted instrument, employed in both psychiatry and medicine in general, is the Medical Outcome Survey. The versions most commonly used are the three Short Form (SF) instruments: SF-36, SF-12, and SF-4 (Ware and Sherbourne 1992; Ware et al. 1996). The advantage of these scales is that they are widely used, so there is a vast amount of data available validating them in a variety of conditions. The disadvantage of the Medical Outcome Survey is that it is relatively insensitive to change with symptom improvement. This is due to the scoring algorithm, which truncates the range of the scale.
2. The second instrument that has been commonly used in a variety of trials is the Quality of Life Enjoyment and Satisfaction Questionnaire (Q-LES-Q). The Q-LES-Q is available in both a long form and a one-page

summary form, which is the most commonly used version of the questionnaire (Endicott et al. 1993; Rapaport et al. 2005). This scale has 14 items that are rated from 1 to 5 and summed to create a total score. There are also two general items; one is general life satisfaction, and the other assesses satisfaction with medication the patient is taking. The short form of the Q-LES-Q is well validated and takes less than 5 minutes to complete.

3. An instrument that is available in both an interview form and a self-report form is the Quality of Well-Being Scale (QWB) (Kaplan 1993; Kaplan and Anderson 1990). This scale has been developed and validated across many medical and psychiatric conditions. The QWB allows one to get a measure of quality-adjusted life-years. The intent of such a scale is to measure the impact of an illness or a number of illnesses on an individual's overall fitness.
4. An additional instrument that has been reported in the depression literature is the Quality of Life in Depression Scale (Hunt and McKenna 1992). Although this is a well-validated instrument, it does not allow one to generalize the impact of illness on quality-of-life dysfunction beyond major depressive disorder.
5. A less formal but ecologically valid approach is to elicit from the patient the three symptoms or life problems that are most debilitating for the patient at the time of initial assessment. These can be symptoms or signs of depressive disorder, functional impairment, or problems affecting quality of life. The patient is then asked to assess his or her symptoms/problems daily. In our practice at Cedars-Sinai Medical Center, we have called this approach the *most troubling symptoms model* for monitoring care.

   During the initial interview, the patient and therapist collaboratively identify and quantify life problems related to the mood disorder on a Likert scale of 1–10. This approach has several strong points. First, if the patient assesses his or her condition daily, it facilitates the engagement of the patient in therapy, because the patient is monitoring problems that he or she has identified as significant. Second, it allows the patient to know that the physician truly hears what the patient's complaints and concerns are. This enhances the therapeutic relationship and adherence to therapy. Third, this being a fine-grained approach to assessing on a daily basis the severity of problems that the patient has identified, it allows the patient and the clinician to discern subtle changes that frequently are missed when patients are assessed weekly or less frequently. This approach facilitates rational discussion between the patient and the clinician about the patient's condition and, when necessary, the need to alter the treatment course. This has proven to be a simple yet effective technique for monitoring both the severity of the illness and the impact of the illness on the patient's life.

In summary, it is clear that a systematic assessment of the signs and symptoms of an illness, as well as the impact of the illness on other aspects of the patient's life, is necessary to maximize the opportunity for treatment gains. The use of either clinician-rated or self-report measures enables physicians to objectively monitor the course of treatment and the benefits of interventions and is essential for the optimal care of the patient.

TREATMENT OPTIONS

The treatment of major depressive disorder is now commonly conceptualized to have three phases: acute treatment, continuation treatment, and maintenance treatment (Frank et al. 1991b). The overall goal of acute treatment is remission. Thus, during acute treatment the patient is vigorously treated with pharmacotherapy, psychotherapy, or a combination of both until all symptoms of the depressive disorder have been eliminated. It is thought that remission is associated with the restoration, over time, of the individual's quality of life and functioning. The consequences of not achieving remission have been discussed previously in this chapter (see "Changes in Conceptualization of Depressive Disorders" and "Disability and Costs Associated With Depressive Illnesses"). They include an increased risk of treatment resistance (Judd et al. 1998b; Paykel et al. 1995), persistence of psychosocial dysfunction (Miller et al. 1998), an increased risk of morbidity and mortality from medical illnesses (Murray and Lopez 1997), and an increased risk of suicide. The focus of continuation treatment is to protect the patient against a relapse back into the current episode of major depressive disorder. Studies have demonstrated clearly that if treatment is discontinued after the acute phase,

more than half of individuals will have a relapse of major depressive disorder (Thase 1999). The goal of maintenance therapy is to prevent a recurrence or new episode of major depressive disorder. Because major depressive disorder is a chronic and recurrent illness for most individuals, full-dose maintenance therapy is essential in order to minimize the risk for and the number of future episodes (Bump et al. 2001; Prien et al. 1984).

Antidepressant Medications

Under ideal circumstances, the choice of an antidepressant medication is a collaborative process between the physician and the patient. Considerations that need to be weighed by the physician and patient can be broadly grouped as patient preferences, pharmacodynamic concerns, and pharmacokinetic concerns. Particularly in the age of direct-to-consumer advertising and the Internet, many patients take an active approach to their pharmacotherapy. Patients either have searched the Internet for information about treatment options for major depressive disorder or have been influenced by the advertisements that they see on television. Thus, many patients come to the initial appointment with their own biases and beliefs about what would be the best treatment option. However, a variety of other patient-related variables may come into play when selecting an antidepressant medication including side effects (especially sexual side effects, weight gain, and insomnia), dietary restrictions, and ease of use (Table 53–7). Addressing these issues with the patient is important to enhance adherence to therapy. Other patient-specific factors that need to be taken into account are the patient's prior history of response to a medication or a family history of response to a certain class of medications. This may influence both the patient and the physician regarding the choice of medication to treat the current depressive episode.

TABLE 53–7. Antidepressant medications

Type	Drug (trade name)	Daily dosing	Pharmacology	Side effects and other concerns
TCA	Amitriptyline (Elavil)	75–300 mg	Inhibits reuptake of 5-HT and NE	Dry mouth, urinary retention, sedation, constipation, weight gain, hypotension, quinidine-like effect on heart conduction
SSRI	Fluoxetine (Prozac)	20–80 mg	Inhibits reuptake of 5-HT	Sexual dysfunction, nausea, diarrhea, insomnia, agitation, tremors, dizziness, rare hyponatremia, rare bruising, discontinuation syndrome, drug–drug interactions
	Sertraline (Zoloft)	25–200 mg		
	Paroxetine (Paxil)	10–60 mg		
	Citalopram (Celexa)	10–60 mg		
	Escitalopram (Lexapro)	5–20 mg		
SNRI	Venlafaxine (Effexor)	37.5–400 mg	Inhibits reuptake of 5-HT and NE	Nausea, insomnia, sedation, sexual dysfunction, sweating, hypertension, discontinuation syndrome
	Duloxetine (Cymbalta)	30–120 mg		
MAOI	Phenelzine (Nardil)	45–75 mg	Irreversibly inhibits MAO from breaking down into NE, 5-HT, and dopamine	Hypotension, weight gain, sedation, dry mouth, sexual dysfunction, dietary restrictions, risk of hypertensive crisis, life-threatening drug–drug interactions
	Tranylcypromine (Parnate)			
	Selegiline (Emsam [transdermal])	20, 30, or 40 mg	At recommended doses, does not inhibit gut	Weight gain, sedation

Type	Drug (trade name)	Daily dosing	Pharmacology	Side effects and other concerns
			MAO-A	
Atypical	Mirtazapine (Remeron)	15–45 mg	Improves 5-HT and NE tone: α_2 presynaptic blocker on NE and 5-HT neurons Blocks 5-HT_{2A}, 5-HT_{2C}, and 5-HT_3 Blocks H_1	Weight gain, sedation, abnormal dreams, dry mouth, hypotension, constipation, rare agranulocytosis
	Bupropion (Wellbutrin)	75–450 mg in three divided doses (maximal single dose, 150 mg) SR 200–450 mg in two divided doses XL 150–450 mg daily	Blocks reuptake of NE Increases dopamine in frontal cortex Blocks dopamine transporter pump	Agitation, restless insomnia, weight loss, anorexia, sweating, headache, tremor, hypertension, rare seizures
	Trazodone (Desyrel)	100–450 mg	Blocks 5-HT_{2A} Blocks 5-HT reuptake	Orthostatic hypotension, nausea, dry mouth, dizziness, rare priapism, occasional sinus bradycardia

Note. 5-HT = 5-hydroxytryptamine (serotonin); 5-HT_{2A} = 5-HT type 2A receptor; H_1 = histamine type 1 receptor; MAO = monoamine oxidase; MAO-A = monoamine oxidase isozyme A; MAOI = monoamine oxidase inhibitor; NE = norepinephrine; SNRI = serotonin–norepinephrine reuptake inhibitor; SR = sustained release; SSRI = selective serotonin reuptake inhibitor; TCA = tricyclic antidepressant; XL = extended release.

Although we have not been able to discern distinct biological subtypes, pharmacogenetics (discussed in more detail below) has now developed to the point that it can inform our therapeutic decisions. The specific pharmacodynamic properties of an agent certainly need to be taken into account when identifying the appropriate medication for an individual. Although the tricyclic antidepressants and the monoamine oxidase inhibitors have a long history of proven efficacy, these classes of agents have fallen out of favor because of their side-effect profiles. The majority of commonly used antidepressants (see Table 53–7) work via one or more mechanisms: 1) inhibition of serotonin reuptake, 2) inhibition of the reuptake of both serotonin and norepinephrine, 3) stimulation of noradrenergic and dopaminergic activity, or 4) α_2 antagonism of noradrenergic and serotonergic neurons. Physicians now can use knowledge about the pharmacodynamics of agents to influence a treatment choice. For example, a clinician is visited by a 50-year-old white male with chronic, persistent depression. The patient is currently complaining of diarrhea and persistent symptoms of depression despite medication with sertraline at a dosage of 200 mg/day. In taking the patient's history, the clinician learns that the patient has had persistent problems with diarrhea and lack of treatment response with three other SSRIs and with both of the FDA-approved serotonin–norepinephrine reuptake inhibitors. In this case, use of an agent like mirtazapine might be preferable.

The pharmacokinetic profile of the agent is another variable that needs to be taken into account in selecting an antidepressant medication. As would be expected, antidepressants differ in their protein binding, rate and mechanism of elimination, half-life, lipophilicity, and effects on other metabolic pathways. Therefore, it is important to carefully determine what other medications the patient may be

taking. Drug–drug interactions may increase blood levels of concomitant medications, and at times those interactions can be unpleasant or even life-threatening.

In summary, the choice of initial antidepressant medication is ideally a collaborative decision-making process between the patient and the physician. It requires an understanding of the patient's preferences, family history, prior treatment history, and current medical conditions; any current medications he or she may be taking; the side-effect profile of the proposed agent; and the pharmacokinetic and pharmacodynamic properties of the compound. Engagement of the patient in this decision-making process is more likely to enhance adherence to the medication regimen.

Pharmacogenetics

There has been recent attention on the field of pharmacogenetics—the concept of tailoring drug therapy to a patient's genetic makeup (Perlis 2007). Currently, tests are available commercially to screen for allelic variation in the CYP450 genes (Roche Diagnostics, Switzerland). These tests purportedly would allow the physician to select an antidepressant dose based on some knowledge of how the medication will be metabolized and possibly eliminated. This application has limitations given that many other factors are involved in drug metabolism besides a patient's genetic makeup, such as smoking status, diet, concurrent treatment therapies, and other environmental and physiological factors.

Other genetic variations that have been demonstrated to be associated with depression or response to therapy include variation in the gene for SSAT—an enzyme responsible for the metabolism of polyamines (Sequeira et al. 2006)—and genetic variation in CRH (Liu et al. 2007; Papiol et al. 2007) or glucocorticoid receptors (Binder et al. 2004; Brouwer et al. 2006; van Rossum et al. 2006), components of the stress response system. These variations may also prove useful in the future for tailoring pharmacological treatments to individual patients.

Of all other genetic variations, the gene encoding 5 HTT (the serotonin transporter) has been the most widely studied. Individuals who carry a specific polymorphic variation are genetically vulnerable to developing depression when exposed to trauma early in life (Caspi et al. 2003; Kendler et al. 2005). Testing for *5-HTT* genetic variation has been used to identify which class of antidepressants should be used to begin treatment (Smits et al. 2007b). In this study, results were positive in that when genetic testing was used to predict the best type of antidepressant to prescribe, 65% of the screened patients were in remission 6 weeks later, compared with 60% of non–genetically screened patients. Future pretreatment genetic testing must be evaluated on a wider scale and must also include a cost assessment. Nevertheless, other studies have demonstrated that such pretreatment genetic screening for the *5-HTT* variation may aid in determining a patient's vulnerability to side effects of pharmacological treatment (Hu et al. 2007; Smits et al. 2007a).

Somatic Therapies

Five somatic therapies have been investigated to various degrees either as monotherapies or as adjuvant therapies for treatment-resistant depression: electroconvulsive therapy (ECT), vagus nerve stimulation (VNS), repetitive transcranial magnetic stimulation (rTMS), deep brain stimulation (DBS), and light therapy. ECT is the best studied of the somatic interventions. It is clearly one of the treatments of choice for individuals with treatment-resistant depression. Although the mechanism of action of ECT is still not well understood, it is a safe and efficacious treatment. In repeated studies, ECT has been found to be more efficacious than placebo (sham ECT) and more efficacious than pharmacotherapy for treatment-resistant patients. (For a review of ECT data from the United Kingdom, see UK ECT Review Group 2003.)

VNS was initially developed for the treatment of epilepsy. In 2005 it was approved by the FDA for use in treatment-resistant depression. The basis of this approval was a study in which patients with

resistant depression who received adjunctive VNS therapy demonstrated statistically significantly greater improvement in both remission rates and response rates than comparably ill patients who did not receive VNS therapy (George et al. 2005). One of the key findings to emerge from these studies of VNS is that its effect may be cumulative and one may not see the full benefit of VNS stimulation until 9–12 months after treatment is begun (Sackeim et al. 2007; Schlaepfer et al. 2008). The most common side effects of VNS therapy are a voice tremor, cough, dyspnea, and neck soreness.

rTMS was first identified as a treatment for depression by a group of NIMH researchers (George et al. 1995). Since that time, several smaller studies have supported the finding that rTMS may be an effective treatment for major depressive disorder (for reviews, see Couturier 2005; George et al 2007). The results of a recent 21-site study that compared rTMS with sham treatment over the left dorsolateral prefrontal cortex indicated a response rate of 24.5% in the depressed group versus 15.1% in the control group (O'Reardon et al. 2007). These findings led to the recent FDA approval of rTMS for the treatment of depression.

DBS is an FDA-approved treatment for severe, intractable Parkinson's disease. It was used in a small open-label study by Mayberg et al. (2005) in which six patients with intractable treatment-resistant depression had electrodes implanted in the subgenual cingulate cortex. At 6-month follow-up, four of the six subjects were judged to be treatment responders.

Older literature suggested that phototherapy might be an effective augmentation therapy for individuals with certain forms of depressive disorders (Kripke 1981; Lewy and Sack 1986). This has been best studied in patients with seasonal affective disorder. Light therapy for 90 minutes per day has been able to effectively treat, and also prevent the development of, depressive disorder (Even et al. 2007; Westrin and Lam 2007). Light boxes are employed by some clinicians to augment typical antidepressant responses.

In summary, at this time few somatic therapies have demonstrated efficacy for treatment-resistant depression. Two approaches are FDA approved, ECT and VNS, and at least three other somatic therapies show potential benefits. It is clear that more work needs to be done investigating somatic options for patients with treatment-resistant depression.

Alternative Therapies

There is a panoply of alternative therapies that are being investigated both as monotherapies and in conjunction with more traditional forms of psychotherapy or pharmacotherapy. The best investigated alternative therapy is exercise. Evidence suggests that exercise performed a minimum of three times a week, the equivalent of walking 2 miles at a pace of 20 minutes per mile or faster, is associated with a significant decrease in symptoms of depression. Preliminary work studying the acute effects of exercise as a monotherapy or as an augmentation strategy suggests that exercise causes a sustained decrease in depressive mood ratings (Antunes et al. 2005; Osei-Tutu and Campagna 2005; Trivedi et al. 2006b, 2006c).

Data investigating the efficacy of massage therapy for the treatment of depressive disorders come mostly from open studies. In these studies, massage seems to decrease measures of depression and anxiety (Field et al. 1996). Yoga is an alternative therapy that has been investigated in small studies contrasting yoga with both pharmacotherapy and ECT. In these small acute trials, yoga did cause a significant decrease in measures of depression (Janakiramaiah et al. 2000; Pilkington et al. 2005) Acupuncture has not yet been demonstrated to have efficacy as an adjuvant therapy or as monotherapy for major depressive disorder. Both a recent Cochrane analysis and recently published results of a large sham-controlled study suggest that acupuncture may not be effective as a treatment for depressive disorders (Allen et al. 2006; Smith and Hay 2005).

Several alternatives to traditional pharmacotherapy show promise. The best studied natural products

are St. John's wort, *S*-adenosyl-L-methionine, and omega-3 fatty acids (Conklin et al. 2007; M. Fava et al. 2005; Mischoulon and Fava 2002; Murck et al. 2005; Stahl et al. 2008). At this time, all three of these treatments show promise and are under investigation in large NIMH-funded trials.

In summary, although there is burgeoning interest in the use of nontraditional somatic and pharmacotherapeutic treatments for major depressive disorder, these therapies require significantly more rigorous investigation.

Psychotherapy for Major Depressive Disorder

Just as our concept of major depressive disorder has evolved over the last few decades, so has our understanding of the goals of treatment and the length of time required for effective treatment. As recently as the 1980s and early 1990s, there was a schism between psychotherapists and practitioners of pharmacotherapy. The field of psychiatry was caught in a miasma of arguments where disciples argued about the relative merits of psychotherapy versus pharmacotherapy (American Psychiatric Association 2000b; Elkin et al. 1989; Jacobson and Hollon 1996). Fortunately, we have made a transition to focus on helping patients attain remission, maintain remission, restore functioning, and enhance quality of life. Controlled studies have demonstrated that psychotherapy, pharmacotherapy, and combined treatment all have a valuable role to play in achieving these goals (Hollon et al. 2005; Keller et al. 2000; Otto et al. 2005).

At this time, practitioners and researchers involved in the study of psychotherapy for major depressive disorder face a variety of issues. Some of the questions that are currently being investigated, and for which we do not have definitive answers, are the following:

- Are there certain patients who are more responsive to psychotherapy than others? If so, are there certain patient characteristics that would predict whether an individual would be more responsive to cognitive-behavioral therapy (CBT) than to some other evidence-based form of psychotherapy such as interpersonal psychotherapy (IPT)?
- What are the attributes of the people who are most likely to benefit from combined therapy?
- If combined therapy is used, must both forms of therapy be continued after a response is achieved in order to sustain the response?
- Evidence-based psychotherapies require much greater participation by the patient, homework assignments, and much more effort than pharmacotherapy. Thus, it is reasonable to ask, are patients willing to accept psychotherapy?
- Another challenge is, how can academic institutions successfully disseminate evidence-based psychotherapies?
- A related challenge is, how can one ensure that therapists are truly adherent to the key principles of the therapy? It is clear that treatment success, to a significant extent, is based on the fidelity of the practitioner to the model.
- An ever-pressing issue is, will insurers and society adequately compensate individuals to perform these time-intensive psychotherapies?

Cognitive-Behavioral Therapy

CBT comprises a constellation of interventions that target, to varying degrees, maladaptive or critical thinking and behavioral patterns that are destructive, such as inactivity, avoidance, and social withdrawal. A great deal of the initial theory and research validating cognitive therapy was performed by Aaron Beck. He was the first to cogently develop and articulate a cognitive model of depression, and he employed rigorous observational research techniques to study the efficacy of his postulated interventions (A. T. Beck et al. 1979). Key to this model is the observation that depressed individuals have negative mental self-representations of the world, themselves, and their future. He postulated that these representations negatively biased information processing. This led him to develop a short-term structured, collaborative, problem-focused, intervention that involves teaching patients

cognitive and behavioral skills to combat depression (A. T. Beck et al. 1979).

One of the key components of CBT is helping patients identify "automatic thoughts"—the negative, depressogenic cognitions that pervade a depressed individual's thinking. By monitoring and recording these thoughts, patients can begin to get a sense of how their thoughts stimulate unpleasant feelings, sensations, and maladaptive behaviors. This allows a patient to learn to evaluate both the accuracy and the value of automatic thoughts and create an environment in which he or she learns to empirically test the accuracy of these thoughts. In the process of doing so, the patient begins to generate balanced and more adaptive cognitions (e.g., "There are many things that I do well in my life"). An important aspect of the cognitive model of depression is the presence of negative self-schemata, that is, feelings of being worthless or helpless (J. S. Beck 1995; Feldman 2007; Jacobson et al. 1996; Kuyken et al. 2007).

The second component of most forms of CBT is the development of behaviorally oriented interventions to target specific symptoms and to enhance rewarding experiences. Interventions like *behavioral activation* can be focused to eliminate target symptoms like inertia or social withdrawal. Another type of behavioral intervention that is commonly employed in CBT is the teaching of problem-solving skills. This entails the breaking down of tasks that feel overwhelming into smaller discrete, manageable goals. An important component of problem-solving skills training is the development of decision-making skills that help individuals formulate a model for weighing the pros and cons of a situation (Feldman 2007; Kuyken et al. 2007).

A number of modifications of classical CBT for depression are currently being investigated and are gaining significant attention. These include the use of behavioral activation as a stand-alone intervention for depression and the development of therapies that promote psychological well-being and that target cognitive reactivity (i.e., the tendency to respond to sad moods with more negative thinking) (Dimidjian et al. 2006). Well-being therapy is based on a theoretical model by Ryff (1989) that emphasizes the promotion of mental health and not merely the amelioration of mental illness. Thus, patients engaged in this therapy become aware of periods of well-being and challenge automatic thoughts and behaviors that interrupt such periods of pleasant emotions (G. A. Fava 1999). Another form of CBT that has become increasingly popular incorporates mindfulness-based interventions into CBT. It can be done either in individual settings or as part of group CBT treatment. This goal of this mindfulness-based approach is to enable patients to become "decentered" with regard to depressogenic thoughts and see them as mental events rather than as accurate reflections of their reality or core aspects of themselves (Kabat-Zinn 1990; Segal et al. 2002). A third form of cognitively based psychotherapy that has gained acceptance in the research community and increasing acceptance in the clinical community is the cognitive-behavioral analysis system of psychotherapy (CBASP). This was initially designed as a treatment for chronic depression that targets problematic interpersonal patterns and uses situational analysis to challenge maladaptive thinking processes (McCullough 2000). One of the key differences between traditional CBT and CBASP is the integration of concepts of transference reactions into the therapy itself (Butler et al. 2006).

This has been an exciting decade of development for CBT. Both the theoretical framework and practice of cognitively based therapies continue to be refined and modified by researchers. This suggests that cognitive-behavioral psychotherapy will play an increasingly important role in the treatment of depression.

Efficacy of CBT

The overwhelming majority of studies investigating the efficacy of CBT for major depressive disorder are outpatient studies. (The few inpatient studies that have been performed usually combined CBT with pharmacotherapy, and the results of these studies are equivocal [de Jong-Meyer et al. 1996; Hautzinger et al. 1996; Miller et al. 1989a, 1989b].) Meta-analyses suggest that CBT and medication

are equally effective in the acute treatment of major depressive disorder (DeRubeis et al. 1999). This is a change from the results of an earlier study, which indicated that CBT was as efficacious as imipramine for treatment of mild and moderate depression but less efficacious for severe forms of depressive disorder (Elkin et al. 1995). This perception was promulgated by the initial analyses of the NIMH Treatment of Depression Collaborative Research Program. These findings were influential in the American Psychiatric Association (2000b) practice guideline recommendation that pharmacotherapy should be the first-line treatment for more severe depression.

CBT with either pharmacotherapy or psychotherapy is also effective for the treatment of moderate to severe depressive disorders, as demonstrated by DeRubeis et al. in a meta-analysis (DeRubeis et al. 1999) and an NIMH-funded clinical trial (DeRubeis et al. 2005). Behavioral activation therapy also has been found to be comparable to medication for the treatment of moderate to severe depression (Dimidjian et al. 2006). Data from one continuation study suggest that patients who receive CBT are more likely to maintain their remission status (with no more than three booster sessions of CBT during the 12-month continuation phase) than patients who responded to acute treatment with medication followed by discontinuation of medication (Hollon et al. 2005). Of course the flaw with many of the early studies is they did not follow the now commonly accepted tenet that appropriate pharmacotherapy requires sustained pharmacotherapy beyond the acute treatment period. Recent data from the NIMH-sponsored University of Pennsylvania–Vanderbilt University–Rush University treatment collaborative show that 1-year relapse rates were equivalent for individuals treated with CBT with up to three optional booster sessions and those maintained on medication over 1 year of follow-up (Hollon et al. 2005).

The number of well-performed studies that have combined antidepressant treatments with CBT is relatively limited. The studies performed to date suggest that there may be a slight advantage for combined treatment over either treatment alone. One very thoughtful large multisite study investigated the use of combined treatment consisting of nefazodone plus CBASP (a therapy for chronic depression that also has elements of IPT) versus CBASP alone or nefazodone alone. In this study, the effect sizes of combined treatment were significantly greater than the effect sizes of either treatment alone (Keller et al. 2000). The size of this study allowed the authors to perform additional analyses to examine whether specific factors might identify those patients best suited for a specific therapy. Secondary analyses of this data set determined that patients with a history of childhood trauma responded better to CBASP, either alone or in combination, than to monotherapy with medication.

Several studies have used some form of CBT either to augment antidepressants' effects or to attempt to treat residual symptoms (G. A. Fava et al. 1997; McPherson et al. 2005; Nemeroff et al. 2003). In the STAR*D study, augmentation of citalopram monotherapy with CBT and augmentation with pharmacological agents produced similar response rates; however, subjects receiving CBT augmentation tended to respond more slowly than those receiving pharmacological augmentation (Thase et al. 2007). CBT has also been used by investigators to treat residual symptoms of depressive disorders (G. A. Fava et al. 2004; Paykel et al. 1999); these studies suggest that adding CBT is more effective than continuing management with medication alone. Furthermore, follow-up evaluation of patients suggests that CBT augmentation may decrease the rate of relapse over time.

In summary, the data suggest that CBT is an effective first-line treatment for individuals with major depressive disorder. Furthermore, CBT may have an important role in facilitating remission for those who have residual symptoms of depression after adequate pharmacotherapy. Intriguing preliminary data suggest that CBT may play a powerful role in decreasing the risk of a relapse or recurrence of major depressive disorder. However, more research is needed.

Interpersonal Psychotherapy

IPT is a brief form of individual psychotherapy that focuses on one of four problem areas during acute treatment: grief, role transitions, role disputes, and interpersonal deficits. Acute therapy is tailored to the patient's specific presenting problems. IPT has been demonstrated to be an efficacious acute treatment both for outpatients and, more recently, for inpatients with major depressive disorder (Frank et al. 1990, 1991a; Luty et al. 2007; Reynolds et al. 1999; Schramm et al. 2007). The majority of studies investigating IPT as a monotherapy have been performed with outpatients. These studies demonstrated that IPT is an efficacious treatment for individuals with recurrent depressive disorder, older individuals with depression, and women with major depressive disorder (Frank et al. 1990, 1991a; Luty et al. 2007; Reynolds et al. 1999). A study of inpatients with either major depressive disorder or bipolar II disorder (in the depressed phase of their illness) reported that the combination of 5 weeks of intensive IPT plus medication was more efficacious than medication and treatment as usual (Schramm et al. 2007). The group receiving combined therapy with IPT was more likely to sustain response and remission at 3-month follow-up than individuals in the medication management group without IPT. However, at 1-year follow-up, the two groups had comparable relapse rates (Schramm et al. 2007).

Ellen Frank and colleagues have been responsible for some of the most thoughtful work investigating the efficacy of IPT as a monotherapy, in combination with pharmacotherapy, and, most recently, as a maintenance therapy. The focus of maintenance IPT is broader than the focus of acute therapy because the goal is to prevent recurrence and to consolidate the gains made in therapy by augmenting the competencies and strengths achieved during acute IPT. Thus, the focus of maintenance IPT is to reinforce skills in coping with interpersonal life events in the four traditionally identified problem areas (grief, role transitions, role disputes, and interpersonal deficits). In a recent study designed to assess the treatment frequency necessary to prevent relapse into depression, Frank et al. (2007) reported that monthly booster sessions were as efficacious as twice-a-month booster sessions in preventing relapse for women who had been responsive to acute IPT as a monotherapy. However, maintenance IPT monotherapy was not efficacious as a relapse prevention technique for women who had initially required pharmacotherapy combined with IPT to achieve remission.

In conclusion, the data are clear that both CBT and IPT can be efficacious as monotherapies for the treatment of major depressive disorder. Growing data suggest that these psychotherapies may be effective not only in the acute treatment of depression but also in the maintenance treatment of depressive disorders. However, we are still not sure how to match the therapy to a specific patient. There is some indication that patients with avoidant or more passive personality styles may be less successfully treated with IPT than with CBT (Joyce et al. 2007). However, crucial issues limit the effectiveness of both of these psychotherapies: patient acceptance (Thase et al. 2007; Wisniewski et al. 2007), therapist training and fidelity to the techniques (Shaw et al. 1999), and public policy that limits reimbursement. Until we have dealt with these challenges, the dissemination and acceptance of evidence-based psychotherapies will be relatively limited.

TREATMENT APPROACHES

Acute Treatment

The goal of acute treatment of an individual with major depressive disorder is to identify a medication or psychotherapy that is effective and treat the individual vigorously enough to help him or her achieve remission. Recently, most of our understanding of acute treatment has been derived from Phase II and Phase III industry-sponsored studies of antidepressants. Many of these short-term studies were designed to differentiate an investigational compound from placebo. The goal of these trials was not to achieve disease remission but rather to demonstrate that the investigational compound was more efficacious than a placebo compound.

For many years, researchers have looked at the concept of *response,* defined as a 50% drop from

baseline ratings of depression, as an indicator of an appropriate acute treatment trial. In most of these short-term studies, active treatment with psychotherapy, pharmacotherapy, or combined treatment was associated with a 60%–70% rate of response. However, it is now believed that remission rather than merely response is the appropriate goal for acute treatment (M. Fava et al. 2003). The majority of studies reporting remission rates have been short-term industry-sponsored trials that involved garden-variety depressive disorders and showed that approximately one-third of individuals achieve remission within 6–10 weeks of treatment. This finding was corroborated by the recent reports from the STAR*D study (Rush et al. 2006b), which showed that approximately 36% of patients achieved remission (as defined by QIDS-SR) with aggressive and vigorous treatment with citalopram.

The major question that has plagued the field of psychiatry has been what to do after an initial treatment intervention is not successful in achieving remission. The STAR*D study is the first large-scale investigation of mood disorders that has systematically attempted to answer this and other key questions. Patients who did not respond to treatment with citalopram were offered the option of allowing the physician to determine the next treatment, switching to another medication or to CBT monotherapy, or augmenting citalopram with psychotherapy or CBT (Rush et al. 2004). The majority of patients wanted to control their treatment course and elected to either switch medications or join the augmentation group (Wisniewski et al. 2007). Patients who chose the switch option were

meetings sponsored by the MacArthur Foundation that were held to review the data about the course and treatment options for major depressive disorder. These meetings led to a series of papers suggesting that major depressive disorder is not a time-limited event for many people but rather a chronic and continuous syndrome that requires more than acute treatment (Frank et al. 1991b; Kupfer 1991). The goals of the continuation treatment phase include the following:

1. The prevention of relapse into an episode of major depressive disorder
2. A consolidation of gains made during acute treatment in terms of symptom reduction
3. The enhancement of quality of life and functioning of the patient

The need for continuation therapy has been documented in hundreds of trials investigating therapy after acute treatment. Thase (1999) estimated that the risk of relapse is at least 50% when pharmacotherapy is discontinued after acute treatment. Although there is no consensus about the time required for continuation treatment, most investigators and clinicians consider between 4 and 9 months of treatment, at the same intensity used in acute treatment, to be a minimal length of time for continuation therapy (Melfi et al. 1998).

Some interesting data suggest that combined therapy may facilitate continued remission; specifically, the combination of psychotherapy and pharmacotherapy may be beneficial (G. A. Fava et al. 1994). At this time, two studies have investigated the need to continue an augmentation therapy that was initially beneficial. Rapaport et al. (2006) studied the value of continuation therapy with risperidone added to antidepressant monotherapy for patients who were resistant to monotherapy but who entered remission with augmentation therapy. In this study, the relapse rates were identical for individuals randomly assigned to continue receiving antidepressants plus augmentation therapy versus those who received antidepressants plus a placebo. Bauer et al. (2000) investigated the value of continued lithium augmentation in patients with resistant depression and reported that continuation therapy with lithium decreased the relapse rate more than placebo augmentation.

Currently, we have more questions than answers about the best approach to treatment during the continuation phase. We do not yet know the appropriate length of time for continuation treatment, nor do we know what the best strategies are if a patient's condition begins to worsen during continuation treatment. However, it is clear that continuation treatment benefits patients by protecting against recurrence of the initial episode of depression and by allowing a consolidation of gains that impact not only symptom control but also quality of life and functioning.

Maintenance Treatment

A growing body of literature suggests that many individuals with major depressive disorder, a chronic and recurrent illness, require maintenance treatment. At this time, we are unable to biologically predict who will require maintenance or lifelong therapy. However, a series of risk factors have emerged indicating which patients may require maintenance therapy; they include the following:

1. A lifetime history of three or more episodes of major depressive disorder
2. The presence of double depression
3. At least two severe episodes of major depressive disorder within the past 5 years
4. Depressive disorders that are complicated by comorbid substance use or anxiety disorders
5. An age greater than 60 years at the onset of major depressive disorder

Most of these predictors come from longitudinal data gleaned from the NIMH Collaborative Depression Study (Keller and Berndt 2002).

The largest body of data about the value of maintenance therapy has come from two large studies that were performed at the University of Pittsburgh. The first study, by Frank et al. (1990), investigated the efficacy of maintenance with pharmacotherapy, psychotherapy, and combined therapy for adults

who had had three or more episodes of major depressive disorder. In this study, the pharmacotherapies, both alone and in combination with ITP, were more successful than ITP alone or placebo. A second analysis from this study (Kupfer et al. 1992) demonstrated that individuals maintained the response to pharmacotherapy when the dosage was kept at the same level used during the acute treatment phase, and attempts to decrease the medication level by 50% led to relapse into major depressive disorder. Reynolds et al. (1999) published the results of a study with a very similar design, with elderly patients with recurrent major depressive disorder. In this study, both pharmacotherapy and psychotherapy maintenance therapies were efficacious in preventing a new episode of depression. There also have been interesting studies investigating the efficacy of fluoxetine, paroxetine, and extended-release venlafaxine as maintenance therapies. These studies also suggest that maintenance therapy is valuable for people with major depressive disorder (Dombrovski et al. 2007; Keller et al. 2007a, 2007b).

As is the case with continuation therapy, there are many unanswered questions regarding maintenance therapy. At this time, no studies have demonstrated what techniques to use if an individual's condition worsens during maintenance therapy. Another question is whether there are certain individuals who might not require lifelong maintenance therapy. A theoretical issue is the concept that medication may "poop out" and become less effective over time (Zimmerman and Thongy 2007). Although it is clear that some patients lapse into a new episode of depression despite the use of maintenance medication, it is not at all clear what the reasons for relapse are. To date, no careful studies have investigated the role of depressive disorders' progression and the need to alter pharmacotherapies. Just as individuals with hypertension, myocardial disease, or diabetes frequently need to have their treatment modified over a period of time, patients with major depressive disorder may need modifications over the course of treatment. We do not know whether this represents a lack of effectiveness of existing pharmacotherapies or the interaction of the aging body with progression of a diseased state.

In summary, although it is clear that maintenance therapy for depression is beneficial to our patients and their families, a great deal more investigation is needed about the necessary length of treatment, what to do when someone's condition worsens, and the underlying biology of the illness and the patient's response to therapy.

CONCLUSION

Over the past decade we have seen remarkable advances in our knowledge about the etiology, pathophysiology, and course of major depressive disorder and the prognosis for patients. The general consensus is that most people with major depressive disorder have a chronic lifelong condition that will wax and wane over time. An increasing body of evidence supports the postulate that some people with major depressive disorder have a disease that varies in presentation and symptom severity after the initial episode. Many people seem to traverse between having a full-blown episode of major depressive disorder and experiencing residual symptoms of depression, euthymia, minor depression, or new depressive symptoms. If the current evidence is correct, it suggests that our treatment approaches must be broadened to take into account both the chronic nature of the illness and its varied presentation. The implications for treatment are twofold: 1) we need to treat people until they achieve complete remission, and 2) we need to consider continuation and maintenance treatment for far more people than we have previously.

Although the field has made significant progress with information from the STAR*D trial, there are many important unanswered questions. We have limited data about the persistence of remission even after vigorous acute treatment. Only one study has investigated the need for continuation augmentation therapy, and that study suggested that it was not of significant value (Rapaport et al. 2006). No studies have addressed how patients whose condition worsens during continuation or maintenance therapy should be managed. However, the future is bright because of advances in basic

biological investigations of depression. Imaging data are beginning to clearly define specific brain regions that seem to be altered in certain individuals with major depressive disorder. Preclinical studies are elucidating the roles of the function of a variety of neurotransmitter and neurohormonal systems in the pathogenesis of depression, including the noradrenergic system, the serotonergic system, the HPA axis, the immune system, and the NMDA system. Thus, with advances in preclinical animal models, clinical research, and genetics, we will begin to identify specific disorders that fall within the current rubric of major depressive disorder. This biologically informed approach to treatment will allow us to develop better and more personalized treatment plans.

Chapter 54. Treatment of Bipolar Disorder

TREATMENT OF BIPOLAR DISORDER: INTRODUCTION

Bipolar disorder is a common, recurrent, often severe psychiatric illness that, without adequate treatment, is associated with high rates of morbidity and mortality (Goodwin and Jamison 2007). In the Global Burden of Disease survey, bipolar disorder was the sixth leading cause of disability worldwide in 1990 and, without improved access to treatment, was projected to remain so well into this century (Murray and Lopez 1996). Morbidity from bipolar disorder often extends well beyond manic, hypomanic, mixed, and depressive episodes. Full recovery of functioning can lag many months behind symptomatic improvement, and repeated episodes can lead to lasting functional impairment (Judd et al. 2005). Recent naturalistic outcome studies indicate that many patients with bipolar disorder spend protracted periods of time neither well nor syndromally ill but rather suffering from chronic subsyndromal, especially depressive, symptoms (Judd et al. 2002, 2003). Bipolar disorder is also among the most heritable of all medical illnesses (Goodwin and Jamison 2007).

The goals of treatment of bipolar disorder are similar to those of management of many chronic illnesses: rapid, complete remission of acute episodes; prevention of further episodes; suppression of subsyndromal symptoms; and optimization of functional outcome and quality of life (Keck et al. 2001). However, the treatment of bipolar disorder is often complicated. Although classified as a mood disorder, bipolar disorder is also characterized by disturbances of behavior, cognition, and perception. Thus, successful treatment requires that these multiple symptom domains be addressed. Treatment is further complicated by the diversity of illness presentation (e.g., pattern, frequency, and severity of episodes; presence of psychosis, comorbid illnesses, acute or chronic environmental stressors) and course among individuals. Some medications have particular efficacy in one phase of illness but not in another, and some may actually increase the likelihood of precipitating a reciprocal mood episode.

The treatment of bipolar disorder has traditionally been divided into the management of acute manic, mixed, and depressive episodes and the prevention of further episodes and symptoms (Hirschfeld et al. 2002). Rush (1999) conceptualized a "strategies and tactics" approach to the management of major depressive disorder, with principles of pharmacotherapy that are readily applicable to bipolar disorder (Table 54–1). In this chapter we review strategies (i.e., what treatments to choose) and tactics (i.e., how to implement these strategies once chosen and what dose and duration of the chosen medication are to be used) for treating bipolar disorder, drawing primarily on data from randomized, controlled trials. Where such data are lacking, strategies based on data from open trials, naturalistic studies, and expert consensus guidelines are included. The treatment of bipolar disorder in children and adolescents is covered elsewhere in this book (see Chapter 63 in this volume, "Treatment of Child and Adolescent Disorders," by Wagner and Pliszka).

TABLE 54–1. Treatment principles for bipolar disorder

Individually tailor guidelines.
Use proven treatments first.
Select best medication that is

Safe and tolerable.

Easiest to use (for the patient).

Easiest to manage (for the physician).

Aim for symptom remission, not just response.

Measure symptomatic outcome.

Remember that no medication is a panacea.

Do not give up.

Recognize that psychosocial restoration follows symptom relief.

Interpersonal, family, educational, and social rhythm–targeted psychotherapies can help.

More chronic illness may respond more slowly.

FORMULATION AND IMPLEMENTATION OF A TREATMENT PLAN

Patients with bipolar disorder enter into treatment at various phases of illness. Regardless of illness phase, treatment begins with a thorough diagnostic assessment (Hirschfeld et al. 2002). In addition to the clinical features of bipolar disorder described in DSM-IV-TR (American Psychiatric Association 2000), patients with bipolar disorder also commonly experience symptoms of anxiety, impulsivity, recklessness, elevated libido, poor insight, inattention, and sensory hyperacuity during manic or mixed episodes (Keck et al. 2001).

Bipolar disorder frequently presents with depressive episodes. A family history of bipolar disorder or early age at onset of depression should raise diagnostic questions about bipolar disorder in an individual presenting for treatment of depression. Studies suggest that 15%–30% of patients treated for apparent major depressive disorder in outpatient settings subsequently receive a diagnosis of bipolar I or II disorder (Manning et al. 1997, 1998). The Mood Disorder Questionnaire (MDQ) is a 13-item self-report screening instrument for bipolar disorder that has been successfully tested in psychiatric clinics (Hirschfeld et al. 2000) and in the general population (Hirschfeld 2002). Bipolar disorder is associated with elevated rates of substance use, anxiety, eating, attention-deficit/hyperactivity, and impulse-control disorders and migraine (Birmaher et al. 2002; McElroy et al. 2001). Thus, the presence of these illnesses should be assessed in patients with bipolar disorder, and conversely, bipolar disorder should be assessed in patients presenting with these other illnesses. Other elements of a complete psychiatric evaluation are summarized in the American Psychiatric Association's (1995) "Practice Guideline for Psychiatric Evaluation of Adults."

The American Psychiatric Association's revised "Practice Guideline for the Treatment of Patients With Bipolar Disorder" (Hirschfeld et al. 2002) lists a number of other important elements in the treatment of patients with bipolar disorder (Table 54–2). Evaluation of safety of the patient and others and determination of the appropriate treatment setting are essential because of the risks of suicide, recklessness, and violence associated with mood episodes (Lopez et al. 2001) (Table 54–3). Establishing and maintaining a treatment alliance are early and ongoing goals to facilitate patient and family education, treatment adherence, and identification of precipitants and prodromal symptoms. Monitoring treatment response and providing illness education can be enhanced by using the Life-Chart Method (Denicoff et al. 2002) or other similar longitudinal self-assessments. In addition, a number of well-validated rating scales exist for monitoring mood symptoms in patients with bipolar disorder cross-sectionally. These include the Young Mania Rating Scale (R. C. Young et al. 1978) for manic symptoms and the Montgomery-Åsberg Depression Rating Scale (Montgomery and Åsberg

1979) for depressive symptoms, among others. Because bipolar disorder can lead to disability and varying degrees of functional impairment in all aspects of life, specific psychotherapeutic and rehabilitation interventions may be needed.

TABLE 54–2. Clinical components of the management of bipolar disorder

Perform a diagnostic evaluation.
Evaluate the safety of the patient and others and determine a treatment setting.
Establish and maintain a therapeutic alliance.
Monitor treatment response.
Provide education to the patient and significant others.
Enhance treatment compliance.
Promote awareness of stress and regular patterns of activity and sleep.
Work with the patient to anticipate and address early signs of relapse.
Evaluate and manage functional impairments.

DEFINITIONS: WHAT IS A MOOD STABILIZER?

The treatment of bipolar disorder is among the most challenging of all treatments for psychiatric illnesses for a variety of reasons, one of which is that some agents effective in the treatment of one pole can exacerbate or cause a switch into another pole. Goodwin and Jamison (2007) have defined *mood stabilizer* as an agent that demonstrates efficacy in the acute treatment of both mania and depression, as well as in the prevention of both types of mood episodes (ideal definition) or an agent that is efficacious in two of these three aspects of treatment (strict definition). In this chapter, we use the term *mood stabilizer* according to the strict definition. To date, there is no ideal agent, although data from randomized, controlled trials suggest that lithium and olanzapine probably come closest.

TREATMENT OF ACUTE BIPOLAR MANIC AND MIXED EPISODES

Manic and mixed episodes are medical emergencies and frequently require treatment in a hospital to ensure safety of patients and those around them. The primary goal of treatment of manic and mixed

episodes is rapid symptom reduction, followed by full remission of symptoms and restoration of psychosocial and vocational functioning (Hirschfeld et al. 2002). These are straightforward goals, but tailoring treatment to specific patients requires consideration of presenting symptoms and their severity (e.g., presence or absence of psychosis, manic or mixed episode, proximal frequency of episodes).

Pharmacotherapy is the cornerstone of treatment of acute manic and mixed episodes and of bipolar disorder in general. A number of medications have demonstrated efficacy in the treatment of acute manic and mixed episodes (Table 54–4). Lithium, divalproex, carbamazepine, olanzapine, risperidone, quetiapine, ziprasidone, aripiprazole, haloperidol, and chlorpromazine have shown efficacy as monotherapy in the treatment of acute mania in randomized, placebo-controlled trials (McElroy and Keck 2000; Perlis et al. 2006c). Although these agents typically produce rates of response (defined as ≥50% reduction in manic symptoms from baseline to endpoint) of approximately 50% in short-term (3- to 4-week) trials, relatively few patients (<25%) actually achieve remission of symptoms within these time intervals while receiving monotherapy with any of these agents. Thus, use of combination therapy is common in clinical practice to improve response and remission rates (Suppes et al. 2005). For example, a number of studies comparing combination treatment with an antipsychotic and lithium or valproate demonstrated superior acute response rates with combination therapy compared with monotherapy (Scherk et al. 2007).

TABLE 54–4. Evidence-based treatment of acute mania

Treatment	Number of positive monotherapy RCTs
Lithium	18
Valproate	9
Carbamazepine	2
Aripiprazole	5
Olanzapine	8
Quetiapine	4
Risperidone	5
Ziprasidone	3
Chlorpromazine	4
Haloperidol	3
ECT	3

Note. ECT = electroconvulsive therapy; RCTs = randomized, controlled trials.

Lithium

Lithium has been a mainstay of treatment for acute mania for more than 50 years, with superior efficacy compared with placebo (Goodwin et al. 1969; Maggs 1963; Schou et al. 1954; Stokes et al. 1971) and comparable efficacy compared with divalproex (Bowden et al. 1994), carbamazepine (Lerer et al. 1987; Small et al. 1991), risperidone (Segal et al. 1998), olanzapine (Berk et al. 1999), quetiapine (Bowden et al. 2005), aripiprazole (Keck et al. 2007), and typical antipsychotics (Garfinkel et al. 1980; Johnson et al. 1976; Platman 1970; Prien et al. 1972; Shopsin et al. 1975; Spring et al. 1970; Takahashi et al. 1975). Lithium exerted improvement in psychotic as well as manic symptoms in these trials. Patients with elated or classic manic symptoms (Bowden 1995) and relatively few lifetime mood episodes (Swann et al. 1999) appear to have better response rates to lithium than do patients with mixed episodes, rapid cycling (Dunner and Fieve 1974; McElroy et al. 1992), and numerous prior

mood episodes.

Lithium response for acute mania can be maximized by titrating to plasma concentrations at the upper end of the therapeutic range (1.0–1.4 mmol/L) as tolerated (Stokes et al. 1976). In randomized, controlled trials, significant clinical improvement usually was reported within 7–14 days among responders (Keck and McElroy 2001). Preliminary data also suggest that the rate of lithium titration may affect response. Goldberg et al. (1998) found that the rapidity of antimanic effect of any mood stabilizer (lithium, valproate, carbamazepine) was proportional to the rate of titration to therapeutic plasma concentrations. Lithium is generally well tolerated during acute treatment, and dosages needed to produce acute antimanic effects may be higher than those needed for maintenance treatment (Bowden 1998). Common side effects associated with acute treatment with lithium include nausea, vomiting, tremor, somnolence, weight gain, and cognitive slowing.

Antiepileptics

Divalproex

Divalproex and related formulations of valproic acid had superior efficacy compared with placebo (Bowden et al. 1994, 2006; Brennan et al. 1984; Emrich et al. 1981; Pope et al. 1991) and comparable efficacy compared with lithium (Bowden et al. 1994; T. W. Freeman et al. 1992), haloperidol (McElroy et al. 1996), and olanzapine (Zajecka et al. 2002) in randomized, controlled acute treatment trials of bipolar manic or mixed episodes. Olanzapine was superior to divalproex in mean reduction of manic symptoms and in proportion of patients in remission at study completion in a second head-to-head comparison trial (Tohen et al. 2002a). Muller-Oerlinghausen et al. (2000) found that the combination of valproate and typical antipsychotics produced significantly lower mean antipsychotic doses and higher response rates compared with placebo added to typical antipsychotics in patients with acute mania.

Unlike lithium, valproate has a comparatively wide therapeutic index. Acute antimanic response is correlated with plasma concentrations between 50 and 125 mg/L, with some evidence of greater response at the upper end of the therapeutic range (Allen et al. 2006; Zajecka et al. 2002). Some patients may require plasma concentrations greater than 125 mg/L, but side effects become progressively more prevalent above this level. Divalproex can be administered at a therapeutic starting dosage of 20–30 mg/kg/day in inpatients with good tolerability, and some evidence indicates a more rapid response than with gradual titration from a lower (e.g., 750 mg/day) starting dose (Hirschfeld et al. 1999; Keck et al. 1993; McElroy et al. 1996; Zajecka et al. 2002).

Divalproex is generally well tolerated during treatment of acute manic or mixed episodes. Common side effects include somnolence, nausea, vomiting, tremor, weight gain, and cognitive slowing. Enteric-coated and extended-release formulations (the latter requiring a 20% dosage increase to yield plasma concentrations equivalent to those with immediate-release formulations) have improved tolerability compared with valproic acid formulations. Rare serious adverse events include pancreatitis, thrombocytopenia, significant hepatic transaminase elevation, hyperammonemic encephalopathy in patients with urea cycle disorders, and hepatic failure.

Carbamazepine and Oxcarbazepine

Until recently, there was a paucity of data from well-designed randomized, controlled trials of carbamazepine in the treatment of mania. However, an extended-release formulation of carbamazepine was superior to placebo in two large randomized, placebo-controlled multicenter trials (Weisler et al. 2004b, 2005). These findings replicated earlier results from a placebo-controlled crossover trial (Ballenger and Post 1978) and comparison studies against lithium (Lerer et al. 1987; Small et al. 1991) and chlorpromazine (Grossi et al. 1984; Okuma et al. 1979). In one small comparison study, valproate was more effective than carbamazepine (Vasudev et al. 2000). Common

side effects of carbamazepine include diplopia, blurred vision, ataxia, somnolence, fatigue, and nausea. Less common side effects include rash, mild leukopenia and thrombocytopenia, and hyponatremia. Rare serious adverse events include agranulocytosis, aplastic anemia, thrombocytopenia, hepatic failure, pancreatitis, and exfoliative dermatitis.

Oxcarbazepine, in contrast to carbamazepine, does not induce its own metabolism, has a lower rate of side effects, and generally has good tolerability (Emrich 1991). Two small randomized, controlled trials of oxcarbazepine in acute mania found oxcarbazepine to be comparable in efficacy to haloperidol and lithium (Emrich 1991; Muller and Stoll 1984). However, both trials were confounded by the use of adjunctive antimanic medications during the trials, and the studies were too small to detect potential differences in efficacy. In the only large randomized, placebo-controlled multicenter trial of oxcarbazepine in acute mania to date, a 7-week study in children and adolescents, oxcarbazepine was not superior to placebo in reduction of manic symptoms (Wagner et al. 2006). Thus, the use of oxcarbazepine in acute bipolar mania has not been substantiated based on evidence from clinical studies but rather is based on putative similarities in mechanism of action with carbamazepine and improved tolerability.

Antipsychotics

Typical (First-Generation) Antipsychotics

Chlorpromazine (Klein 1967) and haloperidol (McIntyre et al. 2005) were superior to placebo in randomized, controlled trials. Typical antipsychotics bear the burden of neurological and neuroendocrinological side effects and may increase the risk of postmanic depressive episodes (Koukopoulos et al. 1980). Thus, typical antipsychotics are commonly regarded as antimanic but not mood-stabilizing agents.

Atypical (Second-Generation) Antipsychotics

The atypical antipsychotics olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole all have demonstrated efficacy in the treatment of acute bipolar mania in at least two randomized, placebo-controlled trials.

Olanzapine was found to be superior to placebo (Tohen et al. 1999, 2000), superior or equal in efficacy to divalproex (Tohen et al. 2002a; Zajecka et al. 2002), and comparable to lithium (Berk et al. 1999; Niufan et al. 2007), risperidone (Perlis et al. 2006a), and haloperidol (Tohen et al. 2003a) in mean reduction of manic and mixed symptoms in 3- to 4-week monotherapy trials. Adjunctive treatment with olanzapine was superior to placebo in patients who were inadequately responsive to lithium or divalproex monotherapy (Tohen et al. 2002b).

In the haloperidol comparison trial, olanzapine was significantly more likely to improve depressive symptoms during the treatment of manic and mixed episodes (Tohen et al. 2003a). In the two placebo-controlled trials, the rate of response was faster with an initial starting dosage of 15 mg/day (Tohen et al. 2000) compared with 10 mg/day (Tohen et al. 1999). Baker et al. (2003) reported significant improvement in agitation in manic patients within 24 hours with the use of rapid initial dosage escalation (20–40 mg/day) compared with usual titration. The intramuscular formulation of olanzapine has also been studied in the treatment of manic agitation (Meehan et al. 2001). In this study, an intramuscular olanzapine dose of 10 mg produced significant improvement compared with placebo and numerically greater improvement compared with intramuscular lorazepam 2 mg at 2 hours following administration. From these studies, it appears that acute antimanic response to olanzapine may be more rapid in patients treated with higher initial doses, with dosage administration in proportion to the degree of psychomotor agitation. In short-term studies, the most common side effects associated with olanzapine were somnolence, constipation, dry mouth, increased appetite, weight gain, and orthostatic hypotension.

Risperidone was superior to placebo (Hirschfeld et al. 2004; Khanna et al. 2005) and comparable to olanzapine (Perlis et al. 2006a), haloperidol (Smulevich et al. 2005), and lithium (Segal et al. 1998) in mean reduction of manic and mixed symptoms as monotherapy in 3- to 4-week trials. Risperidone was superior to placebo as adjunctive therapy with lithium or divalproex in one placebo-controlled trial (Sachs et al. 2002), but not in a second placebo-controlled trial in combination with lithium, divalproex, or carbamazepine (Yatham et al. 2003). However, because this latter study included patients receiving carbamazepine, it is possible that risperidone plasma concentrations may have been significantly reduced in these patients, limiting risperidone's efficacy. The rate of extrapyramidal side effects associated with risperidone was low when the drug was administered at average dosages up to 4 mg/day (Hirschfeld et al. 2004; Sachs et al. 2002; Yatham et al. 2003) but not when administered at average dosages of 6 mg/day or greater (Khanna et al. 2005; Segal et al. 1998). In short-term trials, other commonly occurring side effects included prolactin elevation, akathisia, somnolence, dyspepsia, and nausea.

Quetiapine was superior to placebo as monotherapy in two 12-week studies in adult patients (Bowden et al. 2005; McIntyre et al. 2005) and was comparable to lithium in a 4-week study in adult patients (Li et al. 2008) and to divalproex in adolescents with bipolar mania (DelBello et al. 2006). Similarly, quetiapine was superior to placebo as adjunctive treatment with lithium or divalproex (DelBello et al. 2002; Sachs et al. 2004; Yatham et al. 2004). In two placebo-controlled trials, lithium (Bowden et al. 2005) and haloperidol (McIntyre et al. 2005) were included as active comparators. There were no significant differences in efficacy among patients receiving quetiapine, lithium, or haloperidol, although the trials were not powered to detect such a difference if one existed. The mean modal dose of quetiapine associated with antimanic efficacy in most studies was approximately 600 mg/day (Vieta et al. 2005b). The most common side effects from quetiapine in monotherapy trials were headache, dry mouth, constipation, weight gain, somnolence, and dizziness.

Ziprasidone was superior to placebo (mean dose 120–130 mg/day) in two 3-week monotherapy trials in adult patients (Keck et al. 2003b; Potkin et al. 2005) and comparable to haloperidol in a 12-week trial (Ramey et al. 2003). Ziprasidone was not superior to placebo as adjunctive treatment with lithium in a study designed to prove superior onset of action by 2 weeks of treatment (Weisler et al. 2004a). However, ziprasidone was superior to placebo in reduction of manic symptoms at day 4 in this adjunctive trial. Ziprasidone appears to have dose-related antimanic efficacy within the therapeutic range of 80–160 mg/day. Ziprasidone-related side effects in monotherapy trials included headache, somnolence, extrapyramidal signs, akathisia, and dizziness. The intramuscular (IM) formulation of ziprasidone has also been studied in the treatment of manic agitation (Daniel et al. 2001; Lesem et al. 2001). In these studies, ziprasidone 10–20 mg IM produced significant improvement compared with ziprasidone 2 mg IM at 0.5–4 hours following administration.

Aripiprazole had significantly greater efficacy in the reduction of manic symptoms compared with placebo in three 3-week trials (Keck et al. 2003a, 2007; Sachs et al. 2006) and comparable efficacy with haloperidol (Vieta et al. 2005a) and lithium (Keck et al. 2009) in adequately powered 12-week comparison trials. Aripiprazole was initiated at 15 or 30 mg/day. Common side effects associated with aripiprazole in the placebo-controlled trials were headache, nausea, vomiting, constipation, insomnia, and akathisia.

In the studies of atypical antipsychotics reviewed above, there were no significant differences in response between patients with or without psychotic features or between patients with manic or mixed episodes among all agents, with the exception of trials of quetiapine, many of which excluded mixed patients. Lastly, the prototypical atypical agent clozapine has been reported to have substantial efficacy in a number of large case series of patients with treatment-refractory mania (Calabrese et al. 1996; Green et al. 2000) but has not been studied in placebo-controlled trials in mania.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is an important treatment option for manic patients with severe, psychotic, or catatonic symptoms. ECT was superior in efficacy to lithium (Small et al. 1988) and the combination of lithium and haloperidol (Mukherjee et al. 1994) in prospective comparison studies. In the lithium comparison trial (Small et al. 1988), the presence of depressive symptoms at baseline was the strongest predictor of ECT response. In addition, ECT in combination with chlorpromazine was superior to sham ECT and chlorpromazine (Sikdar et al. 1994). Although these were small studies, their findings are consistent with those of other naturalistic studies of ECT in the treatment of acute mania (Black et al. 1984; Thomas and Reddy 1982). There is a risk of neurotoxicity in patients receiving ECT while also receiving lithium; thus, lithium should be discontinued when ECT is administered (Hirschfeld et al. 2002).

Psychotherapy

Psychotherapeutic interventions in patients with acute mania focus on establishing and maintaining a therapeutic alliance, improving insight, monitoring treatment response, and providing the initial elements of education about bipolar disorder and its manifestations to patients and their families (Hirschfeld et al. 2002). As manic symptoms remit, more attention can be paid to further education, promoting awareness of stressors and sleep hygiene, identifying harbingers of relapse, and assessing need for rehabilitation services.

Novel Treatments

The new atypical antipsychotics paliperidone, asenapine, and bifeprunox and new antiepileptics such as zonisamide, levetiracetam, and acamprosate are being studied as potential antimanic agents. Among these agents, the only randomized, controlled trial reported to date compared asenapine (mean dosage = 18 mg/day), olanzapine (mean dosage = 16 mg/day), and placebo over 3 weeks (Hirschfeld et al. 2007). Both treatment groups displayed comparable reductions in manic symptoms, and both were superior to placebo. By contrast, a number of potential antimanic agents have not demonstrated convincing efficacy in randomized, controlled trials. These include gabapentin (Frye et al. 2000; Pande et al. 2000), lamotrigine (Anand et al. 1999; Frye et al. 2000), topiramate (Kushner et al. 2006), and verapamil (Janicak et al. 1998; Walton et al. 1996).

In two short-term pilot trials, the protein kinase C inhibitor tamoxifen was superior to placebo in reduction of manic symptoms (Yildiz-Yesiloglu 2007; Zarate et al. 2007). The benzodiazepines lorazepam and clonazepam have been studied in a number of randomized, controlled trials in acute mania (Chou et al. 1999) but have not been demonstrated to exert specific antimanic effects. Nevertheless, adjunctive use of benzodiazepines to treat anxiety, insomnia, and agitation in manic patients is often therapeutic.

Monotherapy Versus Combination Therapy of Acute Bipolar Manic and Mixed Episodes

The data reviewed above provide evidence of the efficacy of specific agents administered for adequate treatment trials at therapeutic doses (Table 54–5). Monotherapy with an antimanic agent represents one of two initial options, primarily for patients with less severe manic symptoms. However, combination therapy has generally been demonstrated to have greater and more rapid efficacy than monotherapy (Scherk et al. 2007). Combination therapy may be a particularly useful option in patients with severe manic symptoms or psychosis.

TABLE 54–5. Criteria for minimum adequate trials of antimanic agents

Medication	Definitive (3-week trial)	Probable (2-week trial)
Lithium	≥0.8 mmol/L	≥0.7 mmol/L
Valproate	≥75 µg/mL	≥50 µg/mL

Medication	Definitive (3-week trial)	Probable (2-week trial)
Carbamazepine	≥800 mg/day	≥600 mg/day
Haloperidol	≥0.2 mg/kg/day	≥0.1 mg/kg/day
Chlorpromazine	≥500 mg/day	≥300 mg/day
Olanzapine	≥15 mg/day	≥10 mg/day
Ziprasidone	≥120 mg/day	≥80 mg/day
Risperidone	≥5 mg/day	≥4 mg/day
Quetiapine	≥600 mg/day	≥400 mg/day
Aripiprazole	≥30 mg/day	≥15 mg/day

Source. Adapted from Keck PE Jr, McElroy SL: "Definition, Evaluation, and Management of Treatment Refractory Mania." *Psychopharmacology Bulletin* 35:130–148, 2001. Copyright 2001, MedWorks Media. Used with permission.

To date, mainly combinations of antipsychotics in conjunction with lithium, valproate, and/or carbamazepine have been studied. The efficacy of combinations of lithium, valproate, or carbamazepine versus monotherapy with these agents has not been studied in randomized, controlled trials, although anecdotal evidence suggests that these combinations may have greater efficacy than either agent alone (M. P. Freeman and Stoll 1998). Similarly, there are no data to date to suggest that other than standard therapeutic doses of agents used in combination therapy are needed.

TREATMENT OF ACUTE BIPOLAR DEPRESSIVE EPISODES

For many patients with bipolar disorder, depressive episodes or chronic waxing and waning subsyndromal depressive symptoms dominate their course of illness and constitute a major source of disability (Judd et al. 2002, 2003; Perlis et al. 2006b). In addition, suicide is a substantial risk of untreated bipolar depression. Thus, the goal of treatment of bipolar depression is full remission of symptoms (Hirschfeld et al. 2002). This straightforward goal is complicated by the limited efficacy of many mood stabilizers in bipolar depression (Zornberg and Pope 1993), often requiring the adjunctive use of unimodal antidepressants with the attendant risk of cycle acceleration or switching (Table 54–6). Moreover, there are very little data indicating that the addition of antidepressants to mood stabilizers is more effective than utilization of mood stabilizers alone in alleviating acute bipolar depressive symptoms (Sachs et al. 2007). To date, only quetiapine and combination olanzapine–fluoxetine have indications for the treatment of acute bipolar I depression.

TABLE 54–6. Evidence-based treatment of acute bipolar I depression

Treatment	Number of positive RCTs
Monotherapy	
Quetiapine	2
Lamotrigine	2
Olanzapine	1
Lithium	8
Divalproex	1
Carbamazepine	2
Combination therapy	
Olanzapine–fluoxetine	1

Note. RCTs = randomized, controlled trials.

Special Considerations in Bipolar Depression

Antidepressants and the Problem of Switching

The decision to recommend administration or avoidance of antidepressants often means attempting to walk a therapeutic razor's edge between alleviating depression and triggering mood switching. Thus, recent data regarding the protective effect of mood stabilizers against antidepressant-associated switching and the incidence of switching among antidepressants are important to weigh in these decisions. Until recently, most treatment guidelines recommended avoiding antidepressants and relying on mood stabilizers alone in mild to moderate bipolar depression, and when administering antidepressants for severe or persistent bipolar depression, they recommended withdrawing them as quickly as possible after remission (Ghaemi et al. 2001; Sachs et al. 2000). These recommendations were based on reported antidepressant-associated switch rates, which ranged widely, from 10% to 70% (Thase and Sachs 2000).

Many estimates of the incidence of antidepressant-associated switching were based on naturalistic studies that did not control for the switch rate associated with the illness itself. The switch rates reported in recent randomized, controlled acute treatment (i.e., 6–8 weeks) trials of lamotrigine (Calabrese et al. 1999), quetiapine (Calabrese et al. 2005a; Thase et al. 2006), and olanzapine monotherapy (Tohen et al. 2003c) and of combinations of paroxetine with lithium (Nemeroff et al. 2001), lithium with valproate (L. T. Young et al. 2000), and fluoxetine with olanzapine (Tohen et al. 2003c) ranged from 3% to 8%. In addition, Post et al. (2001) reported a switch rate of 14% (8% hypomania, 6% mania) in a 10-week acute treatment trial comparing bupropion, venlafaxine, and sertraline in combination with mood stabilizers. The switch rate with venlafaxine was significantly higher than that with the other agents (Post et al. 2006), a finding consistent with an earlier report by Vieta et al. (2002), who also found a higher switch rate in patients receiving venlafaxine compared with paroxetine. Thus, with newer antidepressant medications administered in conjunction with mood stabilizers, switch rates appear to be low (Peet and Peters 1995), although switch rates may be slightly higher with dual serotonin and norepinephrine reuptake inhibitors such as venlafaxine. These data are also consistent with the results of several naturalistic studies that found that concomitant administration of mood stabilizers with antidepressants cut the risk of switching by about half (Boerlin et al. 1998; Bottlender et al. 2001). The risk of switching appears to be greater in patients with bipolar I depression than in those with bipolar II depression (Altshuler et al. 2006).

Mood Stabilizers as Antidepressants

Most randomized, controlled trials of bipolar depression involved patients with bipolar I disorder. When bipolar II patients were included, their response usually was not reported separately, except in the quetiapine trials, in which quetiapine was superior to placebo in reduction of depression symptoms in both bipolar I and II patients (Calabrese et al. 2005a; Thase et al. 2006). It is not clear whether patients with bipolar II depression require treatment with a mood stabilizer (Thase and Sachs 2000), although most recommendations suggest that mood stabilizers also form the cornerstone of treatment for patients with bipolar II disorder. Treatment with a mood-stabilizing medication, if a patient is not already receiving one, is usually the first-line treatment for bipolar depression, because the inherent risk of switching is likely to be less with a mood stabilizer alone than with an antidepressant alone or with a combination of a mood stabilizer and antidepressant.

Lithium

Eight of nine placebo-controlled trials conducted in the 1960s and 1970s in patients with bipolar I and II disorders found lithium superior to placebo in acute bipolar depression (reviewed in Zornberg and

Pope 1993). In an analysis of five studies in which it was possible to distinguish "unequivocal" lithium responders from patients who displayed partial but incomplete improvement in depression, Zornberg and Pope (1993) found that 36% had an unequivocal response, compared with 79% who had at least partial benefit. The antidepressant efficacy of lithium also was examined in two studies of paroxetine added to mood stabilizers for bipolar depression (Nemeroff et al. 2001; L. T. Young et al. 2000). Nemeroff et al. (2001) found that patients receiving lithium at plasma concentrations greater than 0.8 mEq/L showed no antidepressant benefit from the addition of paroxetine or imipramine compared with placebo. In contrast, patients receiving lithium at concentrations less than or equal to 0.8 mEq/L showed significant antidepressant benefit from the addition of paroxetine compared with placebo. These data confirm earlier impressions that maximizing lithium levels in patients already receiving lithium, or titrating to levels greater than 0.8 mEq/L when initiating lithium, is important to ensure an adequate trial of lithium for bipolar depression. L. T. Young et al. (2000) found that adding an alternative mood stabilizer (lithium or valproate) to the regimen of patients receiving therapeutic doses of a mood stabilizer but experiencing breakthrough depressive episodes was as effective as adding the antidepressant paroxetine. Although this study was too small (*N* = 27) to detect drug–drug differences in efficacy, the mood stabilizer–mood stabilizer combination was not as well tolerated as the mood stabilizer–antidepressant combination, and the only patient who switched did so during this treatment arm.

Atypical Antipsychotics

Quetiapine

Quetiapine (300 mg and 600 mg/day) was superior to placebo in reduction of depressive symptoms in two large 8-week multicenter trials involving outpatients with bipolar I and II depression (Calabrese et al. 2005a; Thase et al. 2006). Patients receiving quetiapine also demonstrated greater improvement in secondary measures of sleep and anxiety compared with patients receiving placebo. There was no significant difference in efficacy between the two quetiapine dosage groups. However, the rate of side effects was lower in the 300 mg/day groups compared with the 600 mg/day groups. Switch rates were low (3%–4%) across all treatment groups and were not significantly different among the quetiapine and placebo groups.

Olanzapine and Olanzapine–Fluoxetine Combination

Olanzapine and the combination of olanzapine and fluoxetine (OFC) were superior to placebo in reducing depressive symptoms in an 8-week trial of 833 patients with bipolar I depression (Tohen et al. 2003c). However, the OFC was superior not only to placebo throughout the trial but also to olanzapine for weeks 4–8. There were no significant differences in switch rates (6%–7%) among the three groups. Brown et al. (2006) compared OFC with lamotrigine (titrated to 200 mg/day) in a 7-week comparison trial in outpatients with bipolar I depression. Patients receiving OFC displayed greater reduction in depressive symptoms compared with patients receiving lamotrigine, although the lamotrigine group may have had a greater response with a longer trial, given the need for gradual lamotrigine titration. Switch rates were not significantly different between the two groups.

Antiepileptics

Lamotrigine

In an initial large 7-week randomized, placebo-controlled trial, lamotrigine (at 50 mg/day and 200 mg/day) was superior to placebo in patients with bipolar I depression (Calabrese et al. 1999). Switch rates (3%–8%) were not significantly different among the three groups. A second large placebo-controlled, parallel-group, flexible-dose trial involving patients with bipolar I and II depression did not find a significant advantage for lamotrigine over placebo (Bowden 2001). However, in a post hoc

analysis, lamotrigine was superior to placebo in bipolar I patients. Frye et al. (2000) found lamotrigine superior to placebo in improving depression in a double-blind crossover trial in patients with treatment-refractory rapid-cycling bipolar I and II disorders. Lamotrigine was superior to placebo when added to lithium in an 8-week trial in patients with breakthrough depressive episodes (van der Loos and Nolen 2007). Common side effects of lamotrigine in these studies included headache, nausea, infection, and xerostomia. The risk of serious rash from lamotrigine can be reduced by carefully adhering to Physicians' Desk Reference–recommended titration schedules, but patients should be warned of the risk of rash and the need to report it immediately.

Carbamazepine

In two small controlled trials of patients with treatment-refractory bipolar depression, response to carbamazepine was superior to placebo (Post et al. 1986) and lithium (Small 1990). The results of these initial intriguing findings have not been followed up by large placebo-controlled, parallel-group trials.

Divalproex

Two small randomized, placebo-controlled trials of divalproex in the treatment of acute bipolar depression yielded opposite findings. Sachs and Collins (2001) did not find divalproex to be superior to placebo in one pilot trial, whereas Davis et al. (2005) found divalproex superior to placebo in reduction of depressive and anxiety symptoms in a later pilot study. As with carbamazepine, the results of these initial findings have not been followed up by large placebo-controlled, parallel-group trials.

Antidepressants

There is a relative dearth of randomized, controlled trials of antidepressants as monotherapy or in combination with mood stabilizers in bipolar depression (Ghaemi et al. 2001). Thase and Sachs (2000, p. 558) emphasized that "not a single antidepressant medication, nor even a particular class of antidepressant, has been demonstrated to be effective in at least two adequately powered, placebo-controlled clinical trials." Thus, with a thin evidence base, current recommendations regarding the use of antidepressants in conjunction with mood stabilizers for acute bipolar I depression tend toward the conservative (i.e., avoid antidepressants if possible). However, some general impressions can be gleaned from the available clinical trials. First, switch rates of newer antidepressants in short-term trials, in general, appear to be lower than those associated with tricyclic antidepressants (TCAs) in older studies (Thase and Sachs 2000). Second, among all of the antidepressants studied, the most substantial evidence for efficacy rests with the monoamine oxidase inhibitor (MAOI) tranylcypromine (Himmelhoch et al. 1991), but safety concerns often eliminate this agent from first-line therapy choices (Hirschfeld et al. 2002). Bupropion (Sachs et al. 1994) and selective serotonin reuptake inhibitors (SSRIs) (Nemeroff et al. 2001; L. T. Young et al. 2000) are common first-line agents administered in conjunction with mood stabilizers.

Electroconvulsive Therapy

ECT had significantly greater efficacy than MAOIs, TCAs, or placebo in several randomized, controlled trials in patients with bipolar depression (reviewed in Zornberg and Pope 1993). ECT may be particularly indicated for patients with severe, psychotic, or catatonic symptoms.

Psychotherapy

There are very few randomized, controlled trials of any form of psychotherapy for patients with acute bipolar depression. Cognitive-behavioral and interpersonal therapy have demonstrated efficacy in the treatment of unipolar major depression, but these modalities have been examined only in very small preliminary studies in patients with bipolar depression, thus far without conclusive findings (Cole et

al. 2002; Zaretsky et al. 1999).

Novel Treatments

As in the treatment of acute bipolar manic and mixed episodes, there is considerable interest in the potential efficacy of new atypical antipsychotics and antiepileptic agents in the treatment of acute bipolar depression. With the exceptions of olanzapine, quetiapine, aripiprazole, lamotrigine, and gabapentin, these agents have not yet been well studied in randomized, controlled trials in the depressed phase of the illness. In two placebo-controlled trials, aripiprazole-treated patients did not display significantly greater improvement in depressive symptoms compared with patients receiving placebo at the 8-week study endpoint (Thase et al. 2008). Shelton and Stahl (2004) conducted a small pilot study comparing adjunctive treatment with risperidone, paroxetine, or the combination added to a mood stabilizer in outpatients with bipolar I or bipolar II depression. There were no significant differences in efficacy among the three treatment groups, but the study was limited by its small sample size (*N* = 30). McIntyre et al. (2002) found comparable efficacy for topiramate (mean dosage = 176 mg/day) and bupropion sustained-release (mean dosage = 250 mg/day) in an 8-week single-blind comparison trial in 36 patients with bipolar depression receiving mood stabilizers. No switches occurred in either treatment group.

Among other novel treatment approaches, two preliminary placebo-controlled adjunctive trials examined the efficacy and safety of the dopamine D_2/D_3 receptor agonist pramipexole in the treatment of patients with bipolar I and bipolar II depression (Goldberg et al. 2004; Zarate et al. 2004). In both trials, patients receiving pramipexole added to mood stabilizers had significantly greater reductions in depressive symptoms and significantly greater response rates compared with those receiving placebo. Switch rates did not differ significantly from those with placebo.

Stoll et al. (1999) reported significant global improvement in depressive symptoms in patients receiving omega-3 fatty acids compared with placebo. These findings were not replicated in a second placebo-controlled trial (Keck et al. 2006b).

Monotherapy Versus Combination Therapy of Acute Bipolar Depressive Episodes

The "mood stabilizer first" approach has guided most recommendations regarding the acute treatment of patients with bipolar I depression (Thase and Sachs 2000). This approach is supported by at least three lines of evidence: 1) randomized, controlled trials have demonstrated the inherent antidepressant activity of at least some mood stabilizers (lithium, lamotrigine, olanzapine, quetiapine); 2) mood stabilizer monotherapy appears to carry a lower switch risk as compared with mood stabilizer–antidepressant combination therapy; 3) protection against switching can be implemented if the mood stabilizer alone is not adequate and an antidepressant is needed. Lithium, lamotrigine, quetiapine, and olanzapine are mood stabilizers with demonstrated efficacy as monotherapy in acute bipolar depression.

Combination therapy with an antidepressant and a mood stabilizer is an important option in two clinical groups: patients who do not respond adequately to mood stabilizer monotherapy and patients who have moderate to severe bipolar depression (Hirschfeld et al. 2002). Among antidepressant options, paroxetine, fluoxetine, venlafaxine, bupropion, and tranylcypromine are the most well studied in randomized, controlled trials and appear to have a lower switch risk in comparison with TCAs. Although no randomized, controlled trials of pharmacotherapy of psychotic bipolar depression have been conducted, mood stabilizer–antidepressant–antipsychotic and atypical antipsychotic–antidepressant combinations are common clinical approaches (Keck et al. 2004).

MAINTENANCE TREATMENT

Bipolar disorder is a recurrent lifelong illness in more than 90% of the patients who experience a

manic episode (Goodwin and Jamison 2007). Because of the high risk of recurrence and morbidity associated with mood episodes and interepisode symptoms, maintenance treatment is usually recommended after a single manic episode (Hirschfeld et al. 2002). The goals of maintenance treatment include prevention of syndromal relapse and subsyndromal symptoms, optimization of functioning, and prevention of suicide. As with bipolar depression, there are a limited number of randomized, controlled trials of maintenance treatment of bipolar disorder on which to base treatment recommendations (Table 54–7).

TABLE 54–7. Evidence-based maintenance treatment of bipolar disorder

Treatment	Number of positive RCTs
Lithium	8
Lamotrigine	2
Olanzapine	3
Aripiprazole	1

Note. RCTs = randomized, controlled trials.

Lithium

Lithium is the most extensively studied medication in the maintenance treatment of bipolar disorder. Data from randomized, placebo-controlled trials conducted in the 1960s and 1970s indicated that lithium protected against relapse, with a fourfold lower risk compared with placebo at 6-month and 1-year follow-up intervals (Keck et al. 2000). Lithium was superior to placebo in preventing relapse into mania in two randomized, controlled parallel-group trials lasting 18 months (Bowden et al. 2003; Calabrese et al. 2003).

Lithium may also reduce the risk of suicide in bipolar disorder beyond that predicted by the successful prevention of mood episode recurrences (Baldessarini et al. 2003). Moreover, this risk reduction appears to exceed that of treatment by divalproex (Goodwin et al. 2003).

A number of predictors of poor response to lithium maintenance treatment have been identified. These include rapid cycling, multiple prior mood episodes, negative family history of mood disorder, co-occurring alcohol or substance use disorder, and episode sequence of depression–mania–euthymia (Bowden 1995).

The optimal maintenance lithium serum concentration is an important consideration in successful maintenance treatment. Maintenance lithium serum concentrations usually are lower than those required to produce acute antimanic efficacy (Bowden 1998). Studies by Gelenberg et al. (1989) and Keller et al. (1992) found a serum level–response relationship, with levels of 0.4–0.6 mEq/L being associated with 2.6 times the relapse rate and a significantly greater likelihood of experiencing subsyndromal symptoms, compared with levels of 0.8 mEq/L or higher. There was also a serum level–side effect relationship, with patients at higher levels experiencing significantly higher rates of side effects, often leading to discontinuation. Perlis et al. (2002), in yet another reanalysis of the Gelenberg et al. (1989) data, reported that an abrupt drop in serum lithium levels, whether due to random reassignment or to nonadherence, was the most powerful predictor of relapse. In a comprehensive review of this issue, Baldessarini et al. (2002) concluded that levels of 0.6–0.7 mEq/L appear to provide the best efficacy–tolerability range for most patients. The optimal lithium level for many patients will be the level that balances relapse prevention and suppression of subsyndromal symptoms against minimization of bothersome day-to-day side effects.

Antiepileptics

Lamotrigine

Two large 18-month placebo-controlled maintenance trials comparing lamotrigine (200–400 mg/day) with lithium (0.8–1.1 mEq/L) found lamotrigine, but not lithium, superior to placebo in preventing depressive episodes (Bowden et al. 2003; Calabrese et al. 2003). In contrast, lithium, but not lamotrigine, was superior to placebo in preventing manic episodes. Taken together, the results of these two studies suggest that the combination of lithium and lamotrigine might be especially useful in preventing both manic and depressive episodes, although this remains to be established in a randomized, controlled trial. Of the nearly 1,200 patients who received lamotrigine in these trials, 9% had benign rash (morbilliform or exanthematous eruptions), compared with 8% of the 1,056 patients receiving placebo. When patients who received lamotrigine during the open-label run-in phase of the studies were included in the analysis, the total incidence of rash was 13%, with two cases of serious rash requiring hospitalization (Calabrese 2002).

Calabrese et al. (2000) conducted a 6-month placebo-controlled relapse prevention study of lamotrigine (mean dose, 288 mg/day) in 182 patients with rapid-cycling bipolar I and II disorders. There was no significant difference between the lamotrigine and placebo treatment groups in time to need for additional medications for recurrent mood symptoms. However, there was a trend in favor of lamotrigine over placebo specifically in bipolar II patients.

Divalproex

In the only randomized, placebo-controlled maintenance trial of divalproex in bipolar I disorder, there was no significant difference in the time to development of any mood episode among patients receiving divalproex, lithium, or placebo (Bowden et al. 2000). A number of unforeseen methodological limitations in this trial complicated the interpretation of its results. In patients who received divalproex for treatment of the index manic episode in an open treatment period prior to randomization, divalproex was superior to placebo in early termination due to any mood episode (29% vs. 50%) during the subsequent year. This is a clinically relevant observation, since it supports the efficacy of maintaining patients who respond to divalproex for a manic episode. Divalproex was also compared with olanzapine in a 47-week blinded maintenance trial (Tohen et al. 2003b) described earlier. Calabrese et al. (2005b) compared divalproex with lithium in a 20-month study of patients with rapid-cycling bipolar disorder and found comparable relapse rates in both treatment groups.

There are no data regarding the optimal maintenance valproic acid concentration for bipolar disorder. Current practice usually consists of titrating to therapeutic serum concentrations (50–125 μg/mL) and, as with lithium, balancing relapse and subsyndromal symptom prevention against minimization of side effects (Hirschfeld et al. 2002). Treatment with valproate appears to pose an increased risk of polycystic ovarian syndrome (PCOS), although the relationship between PCOS and weight gain as a possible mechanism is unclear (Hirschfeld et al. 2002).

Carbamazepine

Although a number of studies have examined the efficacy of carbamazepine in the maintenance treatment of bipolar disorder, most of these studies yielded results that were difficult to interpret on methodological grounds (Dardennes et al. 1995). Two studies compared carbamazepine with lithium. In the first study, there were no significant differences in relapse rates after 1 year between lithium (31%) and carbamazepine (37%) (Denicoff et al. 1997). In the second trial, lithium was superior to carbamazepine on a number of outcome measures at 2.5 years of treatment (Greil et al. 1997). There are no data regarding serum level–response relationships for carbamazepine maintenance therapy. Denicoff et al. (1997) found that patients receiving the combination of carbamazepine and lithium in the third year of their trial had a better response than patients receiving either agent alone. Greil et al. (1997) found that patients with atypical symptoms (e.g., psychosis) responded better to carbamazepine than to lithium (Greil et al. 1998).

Therapeutic Monitoring of Lithium, Valproate, and Carbamazepine

Once lithium treatment is established at therapeutic plasma concentrations, recommendations for monitoring patients receiving lithium maintenance treatment include creatinine level and thyroid function test, along with a lithium level at least every 6 months initially (Hirschfeld et al. 2002). Thyroid function testing should be especially considered in patients with rapid cycling. Similarly, in patients receiving valproate maintenance treatment, recommendations for ongoing monitoring include obtaining a valproic acid level, hepatic function tests, and complete blood count (CBC) with platelet count approximately every 6 months (Hirschfeld et al. 2002). For carbamazepine, CBC and hepatic function tests are recommended approximately every 3 months (Hirschfeld et al. 2002).

Atypical Antipsychotics

Olanzapine

Olanzapine was comparable to divalproex in a 47-week comparison trial (Tohen et al. 2003b) and to lithium in a 1-year comparison trial (Tohen et al. 2005). Olanzapine received an indication for maintenance treatment in bipolar disorder based on superiority over placebo in prevention of manic and depressive episodes over 48 weeks (Tohen et al. 2006). The combination of olanzapine and lithium or divalproex was superior to placebo and lithium or divalproex in relapse prevention over 18 months in patients who had initially responded to the active combination acutely (Tohen et al. 2002b) and then were rerandomized (Tohen et al. 2004). This is a very clinically relevant finding, since it suggests that patients who respond acutely to olanzapine in combination with lithium or divalproex in the treatment of a manic episode have a lower risk of relapse by staying on such a combination. However, patients in the combination therapy group had twice the weight gain of patients in the monotherapy group.

Aripiprazole

Aripiprazole was superior to placebo in preventing manic relapse over a 6-month follow-up period in patients with bipolar disorder who were initially stabilized on aripiprazole monotherapy for an acute manic or mixed episode (Keck et al. 2006a). There was no significant difference between treatment with aripiprazole and placebo in relapse into depressive episodes; however, the overall low relapse rate into depression of this trial may have been due to the inclusion of patients whose index episodes were manic or mixed, and not depressed.

Electroconvulsive Therapy

The use of ECT in the maintenance treatment of bipolar disorder has never been studied systematically in a randomized, controlled trial. However, a number of naturalistic studies suggest that maintenance ECT may be a useful treatment alternative for patients who are inadequately responsive to pharmacotherapy (Schwartz et al. 1995; Vanelle et al. 1994).

Psychotherapy

Most patients with bipolar disorder experience a common cluster of psychological problems stemming directly from the illness (Table 54–8). A number of specific psychosocial interventions as adjuncts to mood stabilizer therapy have been shown to improve the long-term outcome of bipolar disorder (reviewed in Rizvi and Zaretsky 2007). The best-studied interventions include educational, interpersonal, family, and cognitive-behavioral therapies. Randomized, controlled trials conducted over 1- to 2-year follow-up periods support the efficacy of cognitive-behavioral therapy (Lam et al. 2005), family-focused and related forms of therapy (Clarkin et al. 1990, 1998; Miklowitz et al. 2003; Rea et al. 2003), interpersonal and social rhythm therapy (Frank et al. 2005), and group psychoeducation (Colom et al. 2003) in reducing or delaying mood episode recurrence, increasing treatment adherence, and improving functioning. Family-focused, interpersonal, and social rhythm

therapy were all associated with delaying time to depressive episode relapse compared with brief treatment (Miklowitz et al. 2007). Only one study, of cognitive-behavioral therapy, found no significant benefit overall after 1 year, although post hoc analysis suggested that patients with fewer than 12 lifetime episodes benefited (Scott et al. 2006).

TABLE 54–8. Common psychological issues associated with bipolar disorder

Emotional consequences of manic, mixed, and depressive episodes
Acceptance of and coping with an often chronic mental illness
Effects of stigmatization
Developmental delays or deviations
Fears of recurrence and resulting inhibitions
Interpersonal challenges: marriage, family, pregnancy, child-rearing
Academic and occupational problems
Legal, social, and emotional problems arising from reckless, impulsive, withdrawn, or violent behavior

Novel Treatments

Quetiapine, ziprasidone, risperidone, and paliperidone, as well as new antiepileptics, may be potential long-term mood-stabilizing agents but have yet to be studied in randomized, controlled trials. Clozapine was more effective than "treatment as usual" (combinations of mood stabilizers and typical antipsychotics) in a 1-year study in patients with treatment-refractory bipolar and schizoaffective disorder (bipolar subtype) (Suppes et al. 1999) and represents an important treatment option for patients unresponsive to conventional agents.

TREATMENT CONSIDERATIONS

Monotherapy Versus Combination Therapy

Mood Stabilizers

The optimal pharmacological maintenance treatment of bipolar disorder requires titration of any single mood-stabilizing medication to eradicate subsyndromal symptoms and prevent relapse. However, outcome assessments from randomized, controlled trials and naturalistic studies indicate that only a minority of patients with bipolar disorder experience optimal benefit (no relapse or recurrences, minimal to no subsyndromal symptoms) from monotherapy with any single mood stabilizer. Combination therapy is therefore frequently necessary and is commonplace in clinical practice. Unfortunately, very few studies have addressed specific mood stabilizer combinations, their relative therapeutic advantages, and their tolerability. As described earlier (see "Maintenance Treatment" section earlier in chapter), the combination of olanzapine with lithium or divalproex was significantly more likely to prevent relapse compared with lithium or divalproex (with placebo) in patients initially responsive to the combination (Tohen et al. 2004). In the only other study reported, Solomon et al. (1997) compared the efficacy of lithium alone versus the combination of lithium and divalproex for 1 year in 12 patients. The combination significantly reduced the risk of recurrence of mania or depression but was associated with more side effects. Thus, the clinical practice of combining mood stabilizers has greatly outstripped the limited data available from formal studies. Combinations of lithium and divalproex, lithium and carbamazepine, and divalproex and carbamazepine; triple therapy

with all three agents; and lithium and/or divalproex with atypical antipsychotics, antidepressants, and lamotrigine have all been reported in case series to be useful maintenance treatment strategies (M. P. Freeman and Stoll 1998).

Mood Stabilizers With Antidepressants

Most recommendations regarding the duration of antidepressant treatment (in conjunction with a mood stabilizer) in patients with bipolar depression suggest prompt discontinuation of antidepressants after remission of depression (Ghaemi et al. 2001). Limiting antidepressant exposure is intended to reduce the risk of switching or cycling. However, discontinuation of antidepressants during maintenance therapy may also increase the risk of depressive relapse. Two studies involving different cohorts of bipolar patients treated naturalistically found that termination of antidepressants was associated with a two- to threefold increased risk of depressive relapse after 1 year (Altshuler et al. 2001, 2003). In contrast, antidepressant continuation was not significantly associated with an increased risk of mania. The results of these two studies suggest that the use of antidepressants in combination with mood stabilizers to prevent recurrence of bipolar depression may be indicated and necessary for many patients, particularly patients without a history of or risk factors for rapid cycling (e.g., substance use disorder, thyroid disease). The optimal duration of antidepressant maintenance treatment and possible predictors of switch versus depressive relapse require further study.

Rapid Cycling

Rapid cycling, the occurrence of four or more mood episodes within 12 months (Dunner and Fieve 1974), poses a special challenge. Among mood stabilizers, divalproex and atypical antipsychotics appear to have greater efficacy than lithium in patients with rapid cycling. Lamotrigine is also a treatment option based on the study by Frye et al. (2000), although its long-term benefit in rapid cycling may be limited to bipolar II rather than bipolar I disorder (Calabrese et al. 2000). Because very few randomized, controlled trials are available to inform treatment decisions, most recommendations are empirical. Combinations of mood stabilizers (e.g., lithium and divalproex, divalproex and atypical antipsychotics, lithium and lamotrigine) are often recommended (Hirschfeld et al. 2002).

Co-Occurring Psychiatric Disorders

Among the major psychiatric disorders, bipolar disorder has the highest comorbidity rate (McElroy et al. 2001). Co-occurring psychiatric disorders can affect treatment recommendations, but to date very few studies have specifically addressed the acute and long-term treatment of patients with bipolar disorder and psychiatric comorbidity. In a 6-month placebo-controlled trial in female patients with bipolar II disorder and borderline personality disorder, divalproex was superior to placebo in reducing measures of interpersonal sensitivity, anger, hostility, and aggression (Frankenberg and Zanarini 2002). Lithium was superior to placebo in patients with bipolar spectrum disorder and co-occurring pathological gambling in a 10-week trial (Hollander et al. 2005). Improvement in gambling severity was correlated with improvement in manic symptoms. Salloum et al. (2005) conducted a 24-week placebo-controlled trial of adjunctive divalproex in patients with bipolar I disorder and co-occurring alcohol dependence who were also receiving lithium and psychosocial treatment. Patients receiving divalproex had significantly fewer days of heavy drinking and showed a trend toward fewer drinks per heavy drinking day compared with patients receiving placebo. Lastly, Weiss et al. (2007) compared a specifically developed form of integrated group therapy for patients with bipolar disorder and concurrent substance dependence with group counseling in patients on mood stabilizers over 20 weeks and found significantly fewer days of substance use in the integrated therapy group during treatment and at 3-month posttreatment follow-up.

Mood Stabilizers and Bipolar-Specific Psychotherapy

From the evidence reviewed above regarding the efficacy of several different forms of psychotherapy specifically developed and operationalized for patients with bipolar disorder, it is clear that the combination of one of these forms of psychotherapy with maintenance pharmacotherapy is superior to pharmacotherapy alone in reducing the risk of relapse and recurrence.

CONCLUSION

There have been substantial advances in the pharmacological treatment of bipolar disorder in the past decade. A number of medications have demonstrated efficacy in the treatment of acute mania in placebo-controlled trials, either as monotherapy or as an adjunct to mood stabilizers. In addition, data are available for the first time indicating that combination therapy with an antipsychotic and a mood stabilizer is more rapidly effective, with better overall response rates in acute mania, than either mood stabilizers or antipsychotics alone.

The treatment of bipolar depression remains one of the most understudied aspects of the illness. The "mood stabilizer first" strategy and combined use of mood stabilizers and antidepressants in moderate to severe bipolar depression are common approaches.

Most patients with bipolar disorder require treatment with more than one medication during the course of their illness. The efficacy of combination strategies is only now receiving close scrutiny. Recent studies suggest that the use of combinations of antidepressants and mood stabilizers as maintenance treatment for some patients to prevent depressive relapse may be important.

The role and efficacy of different types of psychotherapy at different phases of illness management in bipolar disorder are now becoming clearly established. These components of treatment are important in educating patients and families, improving insight and treatment adherence, enhancing coping skills, and dealing with the sequelae of mood symptoms and episodes—and, it is hoped, improving functioning and outcome. Treatment advances in bipolar disorder are finally occurring rapidly. Artfully bringing these treatments to patients with bipolar disorder is both the challenge and the reward of helping people manage this illness.

Chapter 55. Treatment of Schizophrenia

TREATMENT OF SCHIZOPHRENIA: INTRODUCTION

Schizophrenia is a debilitating brain disorder characterized by a chronic relapsing and remitting course of psychosis that is superimposed on persistent "deficit" features such as cognitive dysfunction and negative symptoms. It appears to be equally prevalent across geographical and cultural boundaries (see Jablensky et al. 1992), afflicting approximately 1% of the population (Perala et al. 2007).

The etiology and pathophysiology of schizophrenia remain poorly understood, but the importance of genetic factors is consistently supported by twin (Gottesman 1991; Kendler 1983), family (Gottesman 1991; Kendler 1983; Tsuang et al. 1980), and adoption (Kety et al. 1964, 1994) studies. In the past few years, a number of genes have been identified as being associated with schizophrenia. Furthermore, intensive research has focused on trying to understand how these candidate genes may play a role in the pathophysiology of schizophrenia (G. Harrison 2004; P. J. Harrison and Owen 2003; Porteous et al. 2006; Stefansson et al. 2004). Although the heritability of schizophrenia is high, it appears that environmental events, such as stress (Moghaddam and Jackson 2004), or epigenetic factors (E. Costa et al. 2003, 2006; Tsankova et al. 2007) also play an important role in modulating the expression of the disease genes and, therefore, in the development of particular schizophrenia phenotypes. This notion is highlighted by the observation that the concordance rate for schizophrenia in monozygotic twins is far less than 100%; it usually lies between 46% and 53% (Gottesman 1991). The environmental factors that have been suggested to contribute to the pathophysiology of schizophrenia include in utero virus (Browne et al. 2000; Buka et al. 2001; Mednick et al. 1988), toxoplasmosis (Dickerson et al. 2007; Hinze-Selch et al. 2007; Mortensen et al. 2007), malnutrition (A. S. Brown et al. 1996), cannabis use (Macleod et al. 2006), and obstetric or perinatal complications (Cannon 1997; Cannon et al. 2000; Geddes and Lawrie 1995). Although significant progress has been made in recent years toward understanding the neural basis of schizophrenia, the exact cascade of events—for example, how interactions between genes and environmental factors lead to the emergence of the illness—has yet to be elucidated (Ross et al. 2006; Tsankova et al. 2007; Weinberger 1996).

Considerable progress has been made in the pharmacological treatment of schizophrenia since the serendipitous discovery in the early 1950s of chlorpromazine as the first effective antipsychotic medication (Lehmann and Hanrahan 1954). Many other antipsychotic agents, all sharing chlorpromazine's dopamine D_2 receptor–blocking ability, were subsequently developed. These "conventional," or first-generation, antipsychotics are all effective in the treatment of positive symptoms of psychosis, but they all have limited beneficial effects on negative symptoms and cognitive deficits. Furthermore, these first-generation agents commonly produce extrapyramidal side effects (EPS), including parkinsonism, akathisia, and tardive dyskinesia.

Since 1990, a second generation of antipsychotic drugs has become available in the United States. These second-generation agents are also commonly referred to as "atypical" or "novel" antipsychotics, largely because of their reduced propensity, compared with the conventional agents, to cause EPS. It has been postulated that this unique property (i.e., the low risk of EPS) may reflect

the potent serotonin$_{2A}$ (5-HT$_{2A}$) receptor antagonistic effects or, more specifically, the high ratio of 5-HT$_{2A}$ to D$_2$ receptor occupancy of these drugs (Meltzer 1989). More recently, it has been proposed that the rapid dissociation (high dissociation constant) of these drugs from D$_2$ receptors may be another very important pharmacological property that determines "atypicality" (Kapur and Remington 2001; Seeman 2002).

With the introduction and widespread use of the second-generation antipsychotics, the focus of treatment has been gradually expanding beyond targeting psychotic or positive symptoms of the illness alone. Second-generation agents have been reported to improve some aspects of negative symptoms and cognitive impairment—elements of the disorder not typically responsive to first-generation antipsychotics, at least the high-potency ones (see below). An ability to ameliorate cognitive deficits, in particular, would be important, because such deficits have been found to be strong predictors of long-term functional outcome of the illness (M. F. Green 1996; M. F. Green and Nuechterlein 1999). In fact, development of compounds that can improve cognition has rapidly become one of the main foci in schizophrenia research in just the past few years (Fenton et al. 2003; Hyman and Fenton 2003; Marder 2006).

It should be stressed, however, as will be elaborated in this chapter, that although some of the data on the efficacy of second-generation antipsychotics in the treatment of negative symptoms and cognitive impairment are encouraging, they are by no means conclusive. It may be that rational development of yet newer drugs with novel mechanisms may be necessary before negative symptoms and cognitive deficits can be treated in a clinically meaningful manner (Carpenter and Gold 2002; M. F. Green 2002). This drug discovery and development process is likely to rely critically on an improved understanding of the neurobiological basis of both negative symptoms and cognitive deficits.

In recent years, the field has developed a focused interest in early diagnosis and early intervention in patients who are just becoming psychotic. Studies are under way to determine whether it is possible to delay or even prevent the emergence of psychosis. In the years to come, it is likely that this emphasis on early intervention will expand with further research on the treatment of prodromal states, in an attempt to improve the overall course or perhaps even prevent the actual onset of overt illness in individuals who appear likely to develop schizophrenia.

[The authors would like to acknowledge the contribution of Holly L.L. Pierce in the preparation of this chapter.]

CLINICAL MANIFESTATIONS OF SCHIZOPHRENIA

There is a growing consensus, following the seminal work of several investigators (e.g., Andreasen 1985; Crow 1985), that schizophrenia can be conceptualized as a disorder with at least two more or less orthogonal dimensions of symptomatology: positive and negative symptoms. Positive, or psychotic, symptoms usually are the symptoms that first trigger psychiatric attention, and traditionally, the onset of schizophrenia is clinically synonymous with the emergence of overt psychosis. This concept, however, is gradually changing, because accumulating evidence indicates that the schizophrenia disease process probably begins long before the onset of psychosis. For example, existing evidence from animal studies suggests that brain insults occurring during the first trimester of pregnancy and/or during the perinatal period could have late-occurring detrimental effects on the normal functioning of the brain (Bertolino et al. 2002; D. A. Lewis and Levitt 2002; O'Donnell et al. 2002; Waddington et al. 1998; Weinberger 1987). Interestingly, subtle neurological abnormalities, as well as intellectual and cognitive difficulties, have been observed in children who later show symptoms of schizophrenia (Walker et al. 1999). Finally, research suggests that patients begin to experience a gradual decline in their level of social and cognitive functioning for a period of up to 5 years before the onset of overt psychosis. During this time, they characteristically have symptoms that are similar to the negative symptoms of schizophrenia (Cannon et al. 2007; Hafner et

al. 1994, 1999; Yung and McGorry 1996b). Furthermore, it appears that during this prodromal stage of the illness, several regions of the cerebral cortex undergo pronounced volumetric reduction (Borgwardt et al. 2007; Pantelis et al. 2003).

Positive Symptoms

Positive symptoms are perceptual or cognitive features that "normal" individuals usually do not experience. They include hallucinations, delusions, and disorganized thinking, although disorganization also can be conceptualized as an independent symptom dimension (Liddle et al. 1989). As a general rule, positive symptoms tend to respond to treatment with antipsychotic medications; traditionally, they have been the focus of treatment with these medications. Although positive symptoms are dramatic, and while in the midst of them, patients' ability to function is usually severely disrupted, studies have quite consistently shown that such symptoms do not appear to bear any significant association with or predict the long-term functional outcome of the illness (M. F. Green et al. 2000). It also should be emphasized that psychotic symptoms are not specific to schizophrenia; they can occur in a wide spectrum of other psychiatric, neurological, and medical disorders. Therefore, it is essential to rule out other possible causes of psychosis before a diagnosis of schizophrenia is made.

Negative Symptoms

Negative symptoms represent a "loss" of functions or abilities that people without schizophrenia normally possess. They include anhedonia, affective flattening, alogia, avolition, and asociality. Negative symptoms are somewhat associated with intellectual and neurocognitive impairment (Dickerson et al. 1996; Harvey et al. 1998), and they are better predictors of long-term functional outcome and psychosocial functioning of schizophrenia patients than are positive symptoms (Buchanan et al. 1994; Dickerson et al. 1996; Harvey and Keefe 1998). However, neurocognitive deficits, as discussed below, remain the strongest predictors of outcome (M. F. Green 1996). As mentioned above, negative symptoms may have developed long before the actual "onset" of the illness (Hafner et al. 1994, 1999; Yung and McGorry 1996b), which is traditionally defined as the beginning of psychosis. In fact, many prodromal symptoms of schizophrenia may be phenomenologically indistinguishable from negative symptoms. Importantly, EPS produced by antipsychotic medications can sometimes resemble negative symptoms of schizophrenia.

To clarify matters, the concepts of primary versus secondary negative symptoms have been introduced (Carpenter et al. 1988). Thus, *primary* negative symptoms represent the core negative symptoms reflecting the schizophrenia disease process. *Secondary* negative symptoms, on the other hand, may resemble primary negative symptoms, but they are caused by or are secondary to positive symptoms of psychosis or the antipsychotic medications themselves. This distinction has important treatment implications. For example, a reduction in medication dosage may alleviate some secondary negative symptoms, but this strategy is unlikely to have a beneficial effect on primary negative symptoms.

DIAGNOSIS OF SCHIZOPHRENIA

According to DSM-IV-TR (American Psychiatric Association 2000), to make the diagnosis of schizophrenia, there must be evidence of continuous symptomatic disturbance for at least 6 months accompanied by a decline from the premorbid level of functioning. Thus, in line with the Kraepelinian concept (Kraepelin 1919/1971), DSM-IV-TR emphasizes the longitudinal course of deterioration of the illness. This 6-month period can include functional deterioration occurring during the prodromal phase before the onset of overt psychosis. Within the 6-month period, the patient must have two or more of the following symptoms for at least 1 month: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms. If the duration of psychotic symptoms is less than 1 month because of successful treatment with antipsychotic medication, a diagnosis of

schizophrenia still may be made. Of course, before the diagnosis of schizophrenia is made, other medical or psychiatric conditions need to be considered and ruled out.

NEUROCOGNITIVE DEFICITS IN SCHIZOPHRENIA

In the early Kraepelinian formulation of schizophrenia (or dementia praecox), cognitive impairments represented core deficits (Kraepelin 1919/1971). This Kraepelinian concept was somewhat displaced by an emphasis on psychotic symptoms in the diagnosis and treatment of schizophrenia until recently, when the field of schizophrenia research witnessed substantial resurgence of interest in neurocognitive dysfunction in schizophrenia. Research on cognition may facilitate the identification of endophenotypes (i.e., genetic traits) of schizophrenia and also may have significant treatment implications: cognitive deficits are strong predictors of long-term functional outcome of patients with schizophrenia, and unfortunately, they are also among the features that are most resistant to treatment (M. F. Green 1996; M. F. Green et al. 2000). Further research on cognitive deficits may result in the development of more effective pharmacological, cognitive, and psychosocial interventions in the management and perhaps treatment of these deficits.

Schizophrenia appears to be associated with a decline in general cognitive function at some point during the course of the illness. Various studies have shown that this decline may either predate the onset of psychosis (Aylward et al. 1984; David et al. 1997; Nelson et al. 1990; Russell et al. 1997; Simon et al. 2007) or occur concurrently with or subsequent to the first psychotic episode (Nelson et al. 1990). It appears that after this initial decline, the level of cognitive impairment follows a relatively stable course for several decades without evidence of further significant deterioration (Elvevag and Goldberg 2000; Goldberg et al. 1993). Several aspects of cognitive impairment that are well documented in schizophrenia are briefly discussed below.

Verbal Declarative Memory

Among the cognitive functions that are known to be disturbed in schizophrenia, verbal declarative memory impairment, which can be manifested as disturbances in the encoding, storage, and retrieval of mnemonic items, is one of the most consistent findings. It also represents one of the most severe deficits (Saykin et al. 1991, 1994) that is independent of other cognitive impairment, such as attentional deficits. Memory impairment may represent a core feature of the illness (Saykin et al. 1991), one that is stable over time and relatively independent of clinical course (Censits et al. 1997; Gur et al. 1998). It does not appear to be an artifact of antipsychotic medications because memory impairment occurs in drug-naive first-episode patients (Saykin et al. 1994). In addition, it also occurs in otherwise psychiatrically healthy close relatives of schizophrenia patients (Toomey et al. 1998), suggesting that verbal memory impairment may be an endophenotype of schizophrenia. Interestingly, an association between the degree of memory impairment and the severity of negative symptoms has been found (Harvey et al. 1998; Zakzanis 1998). Like memory deficits, negative symptoms also appear to be quite resistant to treatment and are relatively stable during the course of the illness. Thus, memory impairment and negative symptoms in schizophrenia may involve a shared neuroanatomical substrate. Because memory function is largely mediated by medial temporal structures and negative symptoms are generally associated with prefrontal deficits, information-processing disturbances between the prefrontal and the temporal cortices may represent a prominent feature of schizophrenia (Gur et al. 1998; Heckers et al. 1998).

Working Memory

Working memory is the ability to hold information on-line when other perceptual, cognitive, or mnemonic information is not immediately present in order to guide future behavior and action (Baddeley 1986). This function is mediated by a neural system of which the prefrontal cortex is a key component (Goldman-Rakic 1996). There have been robust findings of impaired performance of schizophrenic patients on tasks that tap working memory (Park and Holzman 1992), impairments that

do not appear to be caused by antipsychotic medications (Goldberg and Weinberger 1996). The fact that working memory impairment is also observed in many first-degree relatives of patients with schizophrenia (Park et al. 1995) suggests that this feature, like verbal declarative memory deficits, may conceivably represent an endophenotype of the illness. Finally, working memory has been extensively studied in nonhuman primates, and the neural elements that support working memory are relatively well understood (Fuster 2000; Goldman-Rakic 1996). Interestingly, postmortem studies have found that many of these neural elements appear to be disturbed in schizophrenia (D. A. Lewis and Lieberman 2000; D. A. Lewis et al. 2005).

Executive Function

Traditionally, the term *executive function* has been used to describe the specific role of the prefrontal cortex in the temporal organization, planning, and sequential execution of goal-directed behavior based on representational information that is constantly being generated and updated (Stuss and Benson 1986). Executive function deficits in schizophrenia, such as those tapped by the Wisconsin Card Sorting Test (WCST), have been frequently described. In a series of well-controlled experiments, Weinberger et al. (1986) showed that during the performance of the WCST, normal control subjects differed from schizophrenic subjects by the selective activation of the dorsolateral prefrontal cortex, as shown by a differential increase in the regional cerebral blood flow (rCBF) to this part of the prefrontal cortex. The lack of action of the prefrontal cortex has been referred to as "hypofrontality" (Ingvar and Franzen 1974). This observation was replicated in subsequent studies when the prefrontal cortex was functionally challenged with the performance of cognitive tasks (K. F. Berman and Weinberger 1999; Carter et al. 1998), although negative findings also have been reported (e.g., Frith et al. 1995; Manoach et al. 1999; Spence et al. 1998).

Attention

Attention plays a key role in mediating many cognitive processes. Attention deficits are well documented in schizophrenia and may in part contribute to the many cognitive disturbances seen in this illness (Braff 1993, 1999; Nuechterlein and Dawson 1984). For example, schizophrenic subjects tend to perform poorly on the Continuous Performance Test, a commonly used task to tap sustained attention. Attention deficit in schizophrenia may reflect an underlying "gating" deficit in which patients have difficulties "filtering out" information that is context-irrelevant or distracting (Braff 1993). One of the most consistent findings in patients with schizophrenia is a deficit in the phenomenon of *prepulse inhibition* (PPI). For example, a sound (prepulse) that occurs 30–500 msec before a sudden loud tone (i.e., a stimulus that normally triggers a startle response) will prevent or reduce the amplitude of the startle response (Braff et al. 1992). However, in patients with schizophrenia, this PPI of the response to the stimulus is diminished (Braff et al. 1992). Interestingly, PPI deficits are also observed in unaffected relatives of patients with schizophrenia (Cadenhead et al. 2000), a finding that is consistent with the notion that such deficits may serve as a trait marker or an endophenotype of schizophrenia.

COURSE OF SCHIZOPHRENIA

Schizophrenia is a chronic illness with the onset of psychotic symptoms usually occurring around late adolescence and early adulthood (D. A. Lewis and Lieberman 2000). The age at onset is approximately 5 years later in women than in men (Angermeyer et al. 1990; Faraone et al. 1994; Hambrecht et al. 1992; Szymanski et al. 1995). The onset of illness also tends to be more acute in women, as compared with the typically more insidious onset in men, and women tend to have had a higher level of premorbid functioning. Although there may be no clear sex differences in cross-sectional symptomatology of the illness (Hafner et al. 1993; Szymanski et al. 1995), the differences in the age at onset, tempo of onset, and level of premorbid functioning, all of which are prognostic factors, are consistent with the fact that women in general tend to have a more favorable outcome.

Accumulating evidence suggests that schizophrenia is a neurodevelopmental disorder (D. A. Lewis and Levitt 2002; Murray 1994; Pilowsky et al. 1993; Waddington 1993; Weinberger 1987, 1996). It has been postulated that disturbances in brain development during the first and second trimesters may contribute to the pathophysiology of the illness (Waddington 1993). Other factors such as obstetric complications may further alter the course of brain development (Cannon 1997; Cannon et al. 2000; Geddes and Lawrie 1995). Minor physical anomalies (Lane et al. 1997), neurological soft signs (Browne et al. 2000; Lawrie et al. 2001; Rosso et al. 2000), and neuromotor abnormalities (Walker et al. 1999) have been observed in children who later develop schizophrenia, consistent with the notion that the pathophysiological process leading to schizophrenia appears to have begun much earlier than the onset of psychosis.

For a period of 2–5 years before the onset of the first overt psychotic episode, up to three-quarters of the patients who eventually develop schizophrenia show a wide spectrum of "prodromal" symptoms (Docherty et al. 1978; Freedman and Chapman 1973; Hafner et al. 1992, 1993, 1994; G. Huber et al. 1980; Lieberman 2006; Simon et al. 2007; Varsamis and Adamson 1971; Yung and McGorry 1996a, 1996b). During the prodromal period, behavior changes, such as deterioration in school, work, social, and interpersonal functioning, are often noted. Prodromal symptoms are usually affective or cognitive in nature (e.g., depressed mood, social withdrawal, decreased concentration and attention, decreased motivation, agitation, anxiety, and sleep disturbances). Many of these symptoms are highly reminiscent of and, in fact, perhaps clinically indistinguishable from the negative symptoms and cognitive deficits seen in schizophrenia itself. Other symptoms occurring in the prodromal period, such as suspiciousness, magical thinking, and paranoia, may resemble positive or psychotic symptoms but tend to be transient and not particularly complex; these quasi-psychotic symptoms eventually coalesce into full-blown psychotic symptoms that characterize the onset of the illness.

After the onset of the first episode of psychosis, the course of the illness is often characterized by a gradual and at times continuous deterioration, especially in the first 2–5 years (McGlashan 1998). Some evidence suggests that functional deterioration may be accompanied by a gradual loss of gray matter volume of the cerebral cortex (DeLisi et al. 1997; Kasai et al. 2003a, 2003b; Salisbury et al. 2007; van Haren et al. 2007; Zipursky et al. 1992). In addition, there has been speculation that these observations of functional and structural brain changes after the onset of psychosis may reflect a neurodegenerative process (DeLisi 1999; DeLisi et al. 1997; Lieberman 1999). However, the available evidence in support of the neurodegeneration hypothesis of schizophrenia remains weak (Carpenter 1998; Weinberger and McClure 2002). Conventionally, the hallmark of neurodegeneration is neuronal death, which is generally not believed to be occurring, at least not in large scale, in schizophrenia (Selemon and Goldman-Rakic 1999). However, it is possible that, short of leading to cell death, neuronal injury can be manifested as loss of dendrites and synapses, which can contribute to the observation of progressive gray matter loss. Furthermore, gray matter volume reduction can alternatively be explained as reflecting an exaggerated synaptic pruning process that is normally occurring during the period of late adolescence and early adulthood (Huttenlocher 2002).

After an initial period of functional deterioration, symptoms tend to become more or less stabilized. Some degree of amelioration of positive symptoms (and, to a lesser extent, of disorganization symptoms) may not be uncommon in older patients (Davidson et al. 1995; Harding et al. 1987; Pfohl and Winokur 1982; Schultz et al. 1997). However, findings of amelioration of psychotic symptoms should be interpreted in light of the fact that these are also the symptoms most responsive to treatment with antipsychotic medication, making it difficult to distinguish between the natural course of the disorder and the accumulated response to treatment. Positive symptoms usually respond to treatment, whereas negative symptoms are believed to be relatively treatment resistant and may tend to become increasingly prominent during the course of the illness (Breier et al. 1991).

Many, but not all, studies (Ho et al. 2000) have implied that early intervention during the very first

episode of psychosis could be associated with better overall prognosis, as measured by fewer relapses, shorter duration between initiation of antipsychotic treatment and response, and fewer residual symptoms (Birchwood 1992; Haas et al. 1998; Johnstone et al. 1986; Loebel et al. 1992). However, these same studies also have shown that the time between the onset of symptoms and the patient's first presentation to psychiatric care (i.e., the duration of untreated psychosis) is far from optimal: the average duration of untreated psychosis is about 1–2 years. Thus, a major goal in the treatment of schizophrenia is early recognition of illness and timely treatment.

MANAGEMENT OF SCHIZOPHRENIA

Acute Psychosis

The acute phase of schizophrenia is characterized by psychotic symptoms and often by agitation. Affective symptoms such as depression and mania also may occur. The severity of symptoms may vary widely, requiring careful evaluation to determine the most optimal treatment setting and management strategy. The decision to hospitalize a patient usually is based on whether the patient has the ability to care for him- or herself or whether he or she poses any risks of harm to self or others. Regardless of whether treatment is provided in a hospital or in an outpatient setting, acute psychosis requires use of antipsychotic medication.

Management of an acutely agitated and psychotic patient can pose a challenge. It may be necessary to physically restrain the patient for his or her own safety and also for the safety of others. Medications given orally or, in the event of severe agitation, parenterally may be indicated. Although the practice patterns for treatment of acute psychosis are changing following the introduction of atypical agents, for initial acute management of severe behavioral dyscontrol, many physicians still use a high-potency first-generation antipsychotic either alone or in conjunction with a benzodiazepine (such as lorazepam) and/or an anticholinergic drug (such as benztropine). Prior to medicating a patient, it is important to inquire about a history of allergic or severe adverse reactions to the medications to be prescribed. For example, the clinician should be particularly cautious when deciding to prescribe a high-potency first-generation antipsychotic agent to a patient with a history of acute dystonic reaction and should avoid such agents in a patient with a history of neuroleptic malignant syndrome.

If the patient has a history of treatment with antipsychotic medications, one needs to ascertain whether the current psychosis is the result of noncompliance or a "breakthrough" episode because of loss of therapeutic response to the medications. Noncompliance with antipsychotic medications is common and is one of the major causes of symptom exacerbation or full-blown relapse (Crow et al. 1986; Lieberman et al. 1993; Robinson et al. 1999). Causes of noncompliance vary, but the most common reasons are side effects, lack of insight into the illness, delusional interpretations about medication, substance abuse, and lack of a supportive environment (Kampman and Lehtinen 1999). If the psychotic episode appears to result from medication noncompliance, the clinician may decide to restart the same medications in the patient, but it is imperative to focus on improving adherence by providing psychoeducation to the patient (and family, if available) and discussing with the patient the reasons for nonadherence. Depot medications also should be considered if noncompliance is a persistent or recurring problem. Of course, in the case of apparent breakthrough psychosis, change in the patient's medication regimen may be indicated. Other causes of exacerbation of psychosis may include comorbid substance abuse or dependence and comorbid depression, as well as psychosocial stressors including difficulties with housing, employment, benefits, insurance, disability, family, and friends. Therefore, although medications are undoubtedly the mainstay for initial treatment of psychosis, other treatment such as psychotherapy, group therapy, family therapy, dual-diagnosis treatment, social skills training, and case management are important adjuncts to pharmacological management.

First-Episode Psychosis

Emphasis on the early diagnosis and treatment of the first psychotic episode of schizophrenia arises from the recent evidence from some, but not all (Ho et al. 2000), studies suggesting that the duration of untreated psychosis may be associated with poorer overall outcome (Birchwood 1992; Loebel et al. 1992; Wyatt 1991). One hypothesis to account for this observation is that shortening of duration of untreated psychosis by early treatment with antipsychotics may decrease the long-term morbidity of the illness. An alternative hypothesis is that prolonged duration of untreated psychosis represents a different, more severe form of schizophrenia that, by itself, is associated with poorer outcome (McGlashan 1999). For example, the delay in obtaining treatment may indicate a more insidious course of onset of psychosis, which is thought to be associated with increased long-term morbidity; alternatively, patients who seek treatment earlier may experience a more acute form of psychosis, which has been suggested to be a predictor of better prognosis (McGlashan 1999). This hypothesis, however, was not supported by a study in which the mode of onset of psychosis, whether insidious or acute, was not correlated with outcome (Loebel et al. 1992). In summary, although some studies have indicated that duration of untreated psychosis is correlated with outcome, whether a prolonged duration of untreated psychosis could be a marker or a determinant of poor outcome remains to be elucidated (McGlashan 1999).

Because of the more favorable neurological side-effect profile—mainly the reduced risks of adverse neurological events such as parkinsonism, akathisia, and tardive dyskinesia—the second-generation antipsychotics are often considered for the initial treatment of first-episode psychosis. However, as discussed below, many of these medications carry other medically important side effects, including weight gain. Because patients are likely to require long-term treatment, clinicians should pay close attention to antipsychotic side effects and to their potential morbidity. In general, a conservative titration schedule is appropriate for first-episode patients, in part to minimize side effects but also to take into account that these patients may require only low doses for the control and remission of symptoms (Remington et al. 1998; Robinson et al. 1999; Schooler et al. 2005; Wyatt 1995).

After remission of an initial episode of psychosis in a patient with a diagnosis of schizophrenia, potential discontinuation of medication, even if done very gradually, is controversial and often not attempted. Any decision about this should be made in light of studies showing that the relapse rate is very high after medication discontinuation in first-episode schizophrenia (Crow et al. 1986; Johnson 1985; Kane et al. 1982; Robinson et al. 1999). Gitlin et al. (2001), using a low threshold to define recurrence of symptoms, reported that the relapse rate in the first year after medication discontinuation was 78% and increased to 98% by the end of the second year. Moreover, Robinson et al. (1999) found that the relapse rate among self-selected first-episode patients who discontinued their medication was five times the rate among those who continued taking medication. Studies suggest that relapse rates may be lower if uninterrupted medication treatment occurs for at least 1 year after the resolution of psychosis (Kissling et al. 1991).

If a decision is made to initiate a trial of medication discontinuation, the discontinuation should be done very gradually, and the patient should continue to be monitored closely for an extended period. Fortunately, in one study of medication discontinuation in recent-onset patients (Gitlin et al. 2001), the combination of close clinical supervision after medication discontinuation and rapid reinstatement of treatment at the first signs of symptom exacerbation was able to prevent frank psychosis and rehospitalization in most patients.

Choice of Antipsychotics

Since the early 1990s, second-generation antipsychotics have been used widely with the belief that these agents were more effective, better tolerated, and ultimately more cost-effective than first-generation antipsychotics. However, little data comparing first- and second-generation antipsychotics existed. To address this knowledge gap, the National Institute of Mental Health (NIMH) sponsored the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study (Lieberman et al. 2005). The

study was designed to compare the effectiveness of four second-generation antipsychotics (olanzapine, quetiapine, risperidone, ziprasidone) and a representative first-generation antipsychotic (perphenazine) in "real world" schizophrenia patients. The primary outcome parameter was discontinuation of treatment. Of the 1,432 subjects who received at least one dose, 74% discontinued study medication before 18 months: 64% of subjects on olanzapine discontinued, compared with 74%–82% on perphenazine, quetiapine, risperidone, and ziprasidone. More subjects receiving olanzapine discontinued due to weight gain and metabolic effects, whereas more subjects assigned to perphenazine discontinued due to EPS (Lieberman et al. 2005). Interestingly, individuals assigned to olanzapine and risperidone who were continuing with their baseline medication had significantly longer times until discontinuation than did those assigned to switch antipsychotics (Essock et al. 2006). Phase 2 of the CATIE study included two treatment pathways (efficacy and tolerability) with randomized follow-up medication based on the reason for discontinuation of the previous antipsychotic drug (McEvoy et al. 2006; Stroup et al. 2006). For subjects who failed to improve with an atypical antipsychotic, clozapine was more effective than switching to another atypical antipsychotic (McEvoy et al. 2006), and in patients who failed to respond to perphenazine, olanzapine and quetiapine were more effective than risperidone (Stroup et al. 2006). Moreover, in subjects who discontinued an atypical agent due to tolerability or efficacy but who were unwilling to be randomized to clozapine, risperidone and olanzapine were more effective than quetiapine or ziprasidone (Stroup et al. 2006). Finally, while the CATIE cost-effectiveness analysis found perphenazine to be less costly and similarly effective (based on quality adjusted life-years) than each of the atypical antipsychotics, the authors note that these results cannot be generalized to all patient populations, and they suggest that these findings do not warrant policies that would unconditionally restrict access to a particular medication (Rosenheck et al. 2006).

Similar to the NIMH-sponsored CATIE study, the United Kingdom's National Health Service funded the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS). This study of 227 schizophrenia-spectrum patients randomly assigned to first- and second-generation antipsychotics (other than clozapine) found no difference between the groups in quality of life, symptoms, or health care costs at 1 year (P. B. Jones et al. 2006). The applicability of these results to U.S. populations may be difficult as this study included several medications that are not available in the United States.

Neither the CATIE nor the CUtLASS study addressed the comparative effects of oral and long-acting injectable antipsychotics. Older mirror-image studies in which patients served as their own controls provide evidence of substantial benefit for first-generation long-acting injectable (LAI) antipsychotics over first-generation oral medications (Schooler 2003). Risperidone is the only second-generation antipsychotic currently available in an LAI formulation. Further research evaluating the comparative effects of risperidone LAI to oral atypical agents is needed.

Taken together, the CATIE and the CUtLASS studies indicate that antipsychotic medications are generally effective but have a variety of shortcomings. Moreover, the effectiveness of a given antipsychotic appears to vary according to clinical circumstances, suggesting the need for individualized therapy based on differences in efficacy and tolerability and, perhaps, reflecting why several medication trials may be necessary in the treatment of patients with schizophrenia (Stroup et al. 2007). Additionally, this variation in effectiveness may underlie the increasing use of antipsychotic polypharmacy, for which there is no empirical basis.

Physicians must thoroughly inquire about the patient's past experience with medications and side effects when selecting an antipsychotic, discuss risks and benefits of each treatment option, and consider the patient's preference. Attempts to optimize current medication regimens (e.g., dosage adjustments or psychosocial interventions) may be useful before deciding to switch medications (Essock et al. 2006). Clozapine should be considered for patients who have failed to respond to other second-generation medications. LAI antipsychotics may be considered for patients with poor

adherence. Physicians need to be well informed about the differential tolerability of all antipsychotics. First-generation agents clearly have the highest risk of EPS and tardive dyskinesia (Glazer 2000b; Jeste et al. 1998; Tollefson et al. 1997). Risperidone and the newly available paliperidone tend to elevate serum prolactin levels and may cause EPS at higher doses. Although weight gain and metabolic disturbances are associated with all of the second-generation agents (with the possible exception of ziprasidone and aripiprazole), olanzapine and clozapine appear to have the highest likelihood of causing these side effects (Allison et al. 1999; American Diabetes Association et al. 2004). Sedation is commonly observed in patients receiving quetiapine, olanzapine, or clozapine. Both ziprasidone and paliperidone carry product labeling for QTc prolongation and should be used with caution in patients at risk for QTc prolongation. Finally, clozapine, because of its side effects of agranulocytosis, seizures, and myocarditis, is generally reserved for patients with treatment-resistant illness or suicidality.

Maintenance Treatment

The major goals of maintenance treatment are prevention of relapse and improvement in psychosocial and vocational function. The primary methods used to achieve these goals are, as at all phases, an integration of optimal psychopharmacological and psychosocial treatments. Treatment and prevention of other psychiatric comorbidities, such as substance abuse and dependence, are important aspects of maintenance treatment. Also, with the use of the second-generation antipsychotics in particular, treatment and prevention of medical comorbidities that may be associated with these drugs, as well as those that may result from the lifestyle of some patients with schizophrenia who are given these drugs, have become a very important part of long-term management.

Prevention of relapse improves long-term clinical outcomes (Wyatt et al. 1998) and reduces the associated economic burden of the illness (Bernardo et al. 2006). With each relapse, the time it takes to achieve clinical stability lengthens, with the possible consequence of ultimate unresponsiveness to treatment (Lieberman et al. 1993; Wyatt et al. 1998). Several studies have demonstrated that higher rates of relapse are associated with medication discontinuation (Beasley et al. 2003; Carpenter et al. 1990; Herz et al. 1991; Jolley et al. 1990; Kramer et al. 2007; Muller et al. 1992; Pietzcker et al. 1993; Schooler et al. 1997). All available atypical antipsychotics have been granted U.S. Food and Drug Administration (FDA) approval for the maintenance treatment of schizophrenia. Moreover, some evidence suggests that atypical antipsychotics may be more effective than conventional agents in forestalling relapse (Conley and Kelly 2002; Csernansky et al. 2002; Leucht et al. 2003a; Schooler 2006; Tran et al. 1998). While it is not clear whether this apparent advantage for atypicals over conventional antipsychotics is related to better tolerability and adherence (Leucht 2004), nonadherence to medication is a significant predictor of relapse (Schooler 2006). LAI atypical antipsychotics have the potential to improve medication adherence and thus improve long-term outcomes, but this requires further research. New research on long-term clinical outcomes in patients with schizophrenia will be aided by the newly proposed and validated remission criteria for the disorder (Andreasen et al. 2005; van Os et al. 2006).

An ongoing treatment alliance among the patient, the family, and the treating clinicians is a crucial factor in maximizing medication and overall treatment adherence. Psychoeducation about illness, relapse, and side effects, as well as specific strategies to manage or avoid particular side effects in the context of an ongoing treatment partnership, helps to increase compliance. Medication adherence is the cornerstone of treatment throughout all phases of schizophrenia.

Treatment-Resistant Schizophrenia

Within this chapter, we have emphasized the pervasive nature of negative symptoms and neurocognitive deficits and their resistance to treatment. However, even if we focus only on psychotic symptoms, which tend to respond favorably to antipsychotic medications, at least 30% of patients still

can be classified as having incomplete to poor response to antipsychotics, with persistent psychotic symptoms (Kane et al. 1988, 2007; Tamminga 1999). Furthermore, patients may show differential therapeutic response to medications; the fact that a patient fails to respond to one or two antipsychotic medications does not necessarily imply that he or she will not respond to a third agent. For research purposes, Kane et al. (1988) operationally defined *treatment resistance* as 1) lack of significant response to at least three adequate trials of neuroleptics from at least two different chemical classes in the past 5 years and 2) persistently poor social and occupational functioning.

Most of the available data suggest that clozapine is the most effective drug for treatment-resistant schizophrenia (Kane et al. 2001; S. W. Lewis et al. 2006; McEvoy et al. 2006). However, because of the serious side effects produced by clozapine and the requirement for frequent white blood cell count monitoring, some patients and some psychiatrists are reluctant to use it, and some patients are unable to tolerate it. However, whether the other second-generation agents even approach the effectiveness of clozapine for the treatment of these chronically ill patients is unclear. In studies that have compared the efficacy of risperidone and clozapine in treatment-resistant schizophrenia, risperidone has been shown to be either as effective as (Bondolfi et al. 1998) or less effective than (Breier et al. 1999; Volavka et al. 2002) clozapine. Moreover, patients with treatment-resistant illness may require high doses of risperidone, increasing the likelihood of EPS. Some evidence has indicated that olanzapine at higher dosages (e.g., 30 mg/day) may be as effective as clozapine in improving both positive and negative symptoms (Tollefson et al. 2001; Volavka et al. 2002), although not all studies agree (Buchanan et al. 2005). Other preliminary data also suggest the possible utility of quetiapine, aripiprazole, and ziprasidone in treatment-resistant patients (Emsley et al. 2000; Kane et al. 2006, 2007).

In summary, clozapine remains the primary medication for treatment-resistant schizophrenia, although some studies suggest that other second-generation agents also may have a role in the management of this disorder. Clinically, judicious combinations of antipsychotics from different classes are sometimes used for patients who fail to respond to monotherapy (including those who fail to respond to clozapine), as may the addition of other agents, such as mood stabilizers. Unfortunately, however, no controlled data suggest that any specific combination is more effective than others. Some of the more commonly used regimens include the combination of an atypical agent with a high-potency conventional agent such as haloperidol and the combination of two atypical agents. Clearly, more research is needed to guide treatment in such patients.

Neurocognitive Deficits

Neurocognitive deficits, especially disturbances in executive functioning, memory, and attention (M. F. Green 1996; M. F. Green et al. 2000), are closely associated with the long-term functional outcome of patients with schizophrenia. It appears that second-generation antipsychotics may improve some aspects of cognition in schizophrenia, as found in a meta-analysis of 15 studies on the cognitive-enhancing effects of these drugs (Bilder et al. 2002). In contrast, conventional antipsychotics have usually been believed not to be efficacious in alleviating these deficits (Cassens et al. 1990; Spohn and Strauss 1989), although findings from the CATIE study suggest that at least some of them might be (Keefe et al. 2007). The therapeutic effects of the newer antipsychotics are most notable in measures of verbal fluency and executive functioning, whereas improvement in memory may be more limited. One recently published study suggested that clozapine, olanzapine, and risperidone all showed superiority over haloperidol in the improvement in global neurocognitive measures, including assessments of memory, attention, motor speed, and executive functions (Bilder et al. 2002). However, it must be noted that the available studies are limited, and many are methodologically compromised (Harvey and Keefe 2001). Thus, whether such improvement represents a genuine amelioration of cognitive deficits as a result of correction of the underlying neural system dysfunctions or rather simply epiphenomenal improvement resulting from the differential side-effect profiles

between the first- and the second-generation drugs remains debatable (Carpenter and Gold 2002). Moreover, in contrast to the idea that second-generation drugs are superior to the older drugs in the treatment of neurocognitive deficits, data obtained from the CATIE trial (Keefe et al. 2007) show that at 18 months of treatment, perphenazine was actually more effective than any of the second-generation drugs in improving all domains of neurocognitive deficits (Keefe et al. 2007). The authors postulate that a number of factors could potentially explain this unexpected finding, including sample size, differences between mid-potency drugs such as perphenazine and high-potency drugs (e.g., haloperidol) that were commonly used in prior studies, the "real-world" features of the CATIE sample, and prior drug trials before entering the study (Keefe et al. 2007). Finally, regardless of the comparable efficacy of first- and second-generation compounds, a critical question that remains unanswered is whether any of the apparent statistically significant improvements in neurocognitive deficits measured in the laboratory can actually be translated into improved functional outcomes, for example, in terms of employment, school performance, or social role (for a discussion, see M. F. Green 2002).

PSYCHOSOCIAL TREATMENT OF SCHIZOPHRENIA

Despite the proven efficacy of antipsychotics in the treatment of schizophrenia, most patients continue to have some degree of residual positive symptoms, negative symptoms, and cognitive deficits, and many (even those who take their medications regularly) have difficulty attaining or regaining their desired level of social and occupational functioning. Thus, the optimal treatment of patients with schizophrenia requires the integration of pharmacotherapy with psychosocial interventions that target functional goals. Treatment is ideally offered by a multidisciplinary team that includes, at a minimum, a medication prescriber and a clinician who understands psychosocial rehabilitation but may also include employment and housing specialists. Programs that utilize clinical case managers to directly assist patients in accessing services and to provide the psychosocial interventions are ideal (Rapp and Goscha 2004). To date, several different types of psychosocial interventions have been empirically shown to reduce rates of relapse and rehospitalization, and a variety of treatments may assist patients in acquiring social and vocational skills and possibly in managing residual psychotic symptoms (Bustillo et al. 2001; Lauriello et al. 1999; Penn and Mueser 1996). Furthermore, the interaction between pharmacological and psychosocial treatments appears to be more than additive because each can enhance the effects of the other and affect different domains of outcome (Marder 2000).

Relapse Prevention

It has long been noted that patients with highly critical or overinvolved family members (so-called high-expressed-emotion [EE] families) have a higher risk of relapse (G. W. Brown and Rutter 1966). In a classic study, M. J. Goldstein et al. (1978) reported that a 6-week therapy focusing on teaching families more effective communication dispute-resolution skills reduced relapse rates for up to 6 months. Many other studies have since confirmed the efficacy of family psychoeducation interventions (involving education, training in problem-solving techniques, and/or in cognitive and behavioral management strategies) to prevent relapse and to improve other outcomes (Falloon et al. 1982; Pilling et al. 2002; Pitschel-Walz et al. 2001; Tarrier et al. 1988). In addition, the positive impact of family interventions seems to persist beyond the time of intervention (Sellwood et al. 2001). Finally, despite the fact that families and patients at different stages of the illness may have specific needs and preferences (e.g., first-episode patients may need more intensive and personalized intervention, whereas families of patients with long-term illness may need continuous long-term support [Montero et al. 2005]), the effectiveness of family psychoeducation in preventing relapse has been found to be independent of either the specific form or the intensity of the intervention (Bustillo et al. 2001).

Another psychosocial intervention that has been shown to be effective in preventing relapse or rehospitalization in schizophrenia is assertive community treatment (ACT). This intervention, which

involves intensive multidisciplinary team management and service delivery in both community and inpatient settings, is designed for individuals who experience intractable symptoms and high levels of functional impairment. At least 30 studies of ACT have shown advantages over standard community treatment in reducing symptoms, family burden, and hospitalization and in improving independent living, housing stability, and quality of life (Mueser et al. 1998; Phillips et al. 2001; Stein and Test 1980). However, it appears that the advantages of ACT do not persist after discontinuation of the program, even after prolonged delivery of services. Finally, ACT also does not have much effect on social adjustment or competitive employment.

Improvement of Psychosocial Functioning

Most patients with schizophrenia have personal goals that involve social and occupational functioning in the community. Hence, psychosocial treatment of patients with schizophrenia targets impairments in these areas. While past research (e.g., the Camarillo State Hospital Study [May et al. 1978]) showed that dynamic psychotherapy was unsuccessful in the treatment of patients with schizophrenia, other forms of individual and group psychotherapy may improve social adjustment and symptom management. In a 3-year study, Hogarty et al. (1997a) found that weekly individual personal therapy, in which an incremental psychoeducational approach based on the patient's phase of recovery was used, had a significant advantage over supportive therapy, family therapy, and combined treatment in improving social adjustment. Yet personal therapy did not appear to be more effective than the other treatments in preventing relapse (Hogarty et al. 1997b). Interestingly, cognitive-behavioral therapy (CBT) may have a role in the management of persistent psychotic symptoms, particularly delusions, in patients with schizophrenia (Chadwick et al. 1994; Granholm et al. 2005; Tarrier et al. 2000). CBT involves the use of techniques such as distraction, cognitive reframing of psychotic beliefs or experiences, and verbal challenge followed by reality testing (Penn and Mueser 1996). Review and meta-analyses of CBT for psychosis suggest a positive effect, although not for reducing relapse (Bellack 2004; C. Jones et al. 2004; Pilling et al. 2002). Further study is needed to demonstrate the efficacy of this treatment paradigm for the management of psychotic symptoms.

Social skills training (SST) is one treatment strategy to help individuals acquire interpersonal disease management and independent living skills that can be delivered in the context of a comprehensive treatment approach. Reviews of SST (Bellack and Mueser 1993; Kopelowicz et al. 2006) have described three models of SST: basic, social problem solving, and cognitive remediation. Within the *basic model,* complex social scenarios are broken down to simpler components, the therapist models correct behaviors, and the patient learns through repeated role-play. This model has been shown to be potentially effective in improving specific social skills for 1 year (Bellack and Mueser 1993). Additionally, the combination of this form of SST with antipsychotic medication appears to be more effective than medication alone in reducing relapse, provided weekly SST is maintained (Hogarty et al. 1986). However, despite skill acquisition, this learning does not appear to generalize to improved social competence within the community (Dilk and Bond 1996).

The *social problem-solving model* focuses on impaired information processing, which is thought to cause social skills deficits, in hopes of achieving a generalized improvement in social adjustment. This model targets symptom and medication management, recreation, basic conversation, and self-care in educational modules, and it has been shown to be effective in enhancing skills (Eckman et al. 1992), although improvements in adaptive functioning within the community are still modest (Liberman et al. 1998; Marder et al. 1996). To enhance generalization to community functioning, interventions that utilize cueing and support in everyday community interactions by "indigenous supporters" such as clinicians, friends, or family seem to improve transfer of newly learned social skills to everyday community interactions (e.g., Glynn et al. 2002).

Finally, the *cognitive remediation model* of SST targets more fundamental cognitive deficits, in areas

such as attention, memory, and planning, with the aim of supporting more complex cognitive processes used in learning social skills. Although initial studies following this model have shown some benefit on basic cognitive processes (Brenner et al. 1992), small studies of more complex cognitive and social skills have been mixed (Hodel and Brenner 1994; Spencer et al. 1994; Wykes et al. 1999). One study of cognitive enhancement therapy, an integrated approach to the concomitant training of neurocognitive and social cognitive abilities as well as social skills, showed improvement in social adjustment (Hogarty et al. 2004) that persisted over 3 years (Hogarty et al. 2006).

Recent work to improve social functioning has focused on social cognition, the capacity to perceive the intentions and dispositions of others (Penn et al. 2006). Interventions targeting social cognition attempt to improve areas that are problematic in individuals with schizophrenia: 1) theory of mind (the ability to represent the mental states of others and make inferences about another's intentions); 2) attributional style; and 3) the ability to perceive facial affect in others. A preliminary study of social cognition and interaction training during 18 weekly sessions comprised of emotion training, figuring out situations, and integration of skills into real life suggests that this may be a promising approach for improving interpersonal functioning and for directly managing symptoms of psychosis (Combs et al. 2007).

Illness management and recovery (IMR) is a manualized package of empirically supported approaches (psychoeducation, cognitive-behavioral approaches for medication adherence, relapse prevention planning, SST, and coping skills training) delivered in weekly group or individual sessions that are utilized with a recovery focus that targets each individual's personal life goals (Mueser et al. 2006). Preliminary research shows that this combination of approaches results in improved symptoms and community functioning (Mueser et al. 2006).

Whereas family psychoeducation, CBT, SST, and IMR may improve symptoms and/or social functioning, they do not appear to affect employment status. In addition, traditional vocational rehabilitation programs have assisted with transitional and sheltered employment, but they have not been successful in helping patients with schizophrenia to obtain and maintain competitive employment (Lehman 1995). However, more than 14 studies suggest that supported employment programs, which use rapid job searches, on-the-job training, continuous job support, and integration with mental health treatment, are more effective than traditional methods in helping patients obtain competitive employment (Bond 2004). Research is currently under way to investigate modifications of supported employment, the role of cognitive remediation (McGurk et al. 2007), and other strategies to improve the ability of supported employment to help patients maintain employment.

In addition to employment, the ability to maintain a residence in the community is an important marker of community functioning and a frequently voiced personal goal of patients with schizophrenia. A variety of approaches have been studied to help these patients obtain and maintain stable community residential tenure. Simple provision of access to affordable housing by Section 8 certificates improves housing stability (Hurlburt et al. 1996b). Supported housing, broadly defined as access to independent housing of the patient's choice (often supported with housing subsidies) that is coupled with access to community mental health and support services, improves residential stability and reduces hospitalization (Rog 2004). ACT for homeless individuals has also been shown to reduce homelessness (Coldwell and Bender 2007).

As multiple effective psychosocial interventions exist and are still being developed, the choice of which intervention to apply should depend not only on therapeutic efficacy but also on each individual's goals and preferences. Patients and their families need to be given information about treatment options and should be engaged in discussions with their treatment providers about how treatments can be useful in the context of an individual's symptoms, comorbidities, and needs and preferences.

MANAGEMENT OF MEDICAL COMORBIDITY

Obesity, Metabolic Syndrome, and Diabetes Mellitus

Medication side effects, as well as lifestyle and disease factors, place patients with schizophrenia at increased risk of developing obesity and metabolic side effects, including glucose intolerance, type 2 diabetes, diabetic ketoacidosis, and hyperlipidemia (Dixon et al. 2000; Meyer and Koro 2004; Wirshing et al. 2002, 2003). While clinically significant weight gain occurs in a substantial proportion of patients receiving an antipsychotic medication (Baptista 1999), a convincing body of evidence indicates that certain atypical antipsychotics cause more weight gain than other agents (Allison et al. 1999; Lieberman et al. 2005; Wirshing et al. 1999). A large meta-analytic study of atypical and typical antipsychotics (Wirshing et al. 1999) found a mean weight gain of 9.8 lbs with clozapine, 9.1 lbs with olanzapine, and 4.6 lbs with risperidone, compared with 2.4 lbs with haloperidol, while the atypical antipsychotic ziprasidone was associated with a less than 1-lb weight gain. Furthermore, the CATIE study demonstrated a greater than 7% weight gain from baseline in 30% of patients receiving olanzapine, 16% of those receiving quetiapine, 14% of those receiving risperidone, 12% of those receiving perphenazine, and 7% of those receiving ziprasidone (Lieberman et al. 2005).

Weight gain induced by antipsychotic medication is usually most rapid early in treatment and may plateau after 1–2 years (Allison et al. 1999; Stanton 1995). Young patients and those with a low baseline body mass index may be at increased risk for weight gain (Kinon 1998). This noticeable and often unacceptable side effect of antipsychotics may contribute to medication noncompliance and increase the risk of obesity-related comorbidities, such as diabetes and adverse serum lipid profile (Allison et al. 1999; A. I. Green et al. 2000).

Diabetes mellitus is estimated to occur two to four times more frequently in patients with schizophrenia compared to the general population (Dixon et al. 2000; Goff et al. 2005; Henderson et al. 2000; Mukherjee et al. 1996; Wirshing et al. 1998). While the risk of diabetes in schizophrenia is likely multifactorial, accrued evidence indicates that atypical antipsychotics are associated with glucose dysregulation (Jin et al. 2004). Several case reports (Koller and Doraiswamy 2002; Koller et al. 2001, 2003), retrospective studies (Dixon et al. 2000; Wirshing et al. 2002), epidemiological investigations (Gianfrancesco et al. 2002), and limited prospective studies (Henderson et al. 2000) of hyperglycemia, new-onset diabetes mellitus, and diabetic ketoacidosis led to heightened attention to and concern over the metabolic effects of atypical antipsychotics, resulting in the issuance of warnings by regulatory authorities and class labeling (Jin et al. 2004). Moreover, in 2004 the American Psychiatric Association, together with the American Diabetes Association, published consensus guidelines on monitoring and described the differential risk of metabolic effects for the atypical antipsychotics (American Diabetes Association et al. 2004). Clozapine and olanzapine are described as having the greatest effect on weight (with increased risk for diabetes), whereas risperidone and quetiapine are described as having an effect on weight (but with unclear risk for diabetes). Aripiprazole and ziprasidone are described as having small or no effect on weight and without risk for diabetes.

Certain atypical antipsychotics (particularly clozapine, olanzapine, and quetiapine) and low-potency conventional agents have been shown to be associated with hyperlipidemia (Henderson et al. 2000; Meyer and Koro 2004; Osser et al. 1999), whereas ziprasidone and aripiprazole do not appear to carry this adverse effect (Kingsbury et al. 2001; Meyer and Koro 2004). The co-occurrence of atherogenic dyslipidemia with abdominal adiposity, insulin resistance, impaired fasting glucose or overt diabetes mellitus, and hypertension constitutes the cluster of clinical features known as the metabolic syndrome, or syndrome X. Given the well-established and close relationship between metabolic syndrome and coronary heart disease (Isomaa et al. 2001) and the growing awareness of a range of metabolic issues in patients with schizophrenia, researchers and clinicians are now focusing on identifying the metabolic syndrome in patients with schizophrenia. Baseline data from the CATIE study

indicated that more than 40% of subjects had metabolic syndrome. Moreover, the CATIE males were 138% more likely to have metabolic syndrome than matched controls, and the CATIE females were 251% more likely to have metabolic syndrome than matched controls (McEvoy et al. 2005).

To minimize iatrogenic medical problems and to ensure optimal treatment outcome, prevention and management of weight gain and obesity-related conditions in patients with schizophrenia are essential. In addition to receiving ongoing education about the potential for weight gain, patients should be counseled about dietary choices, encouraged to exercise, and weighed frequently. In a recent review of behavioral interventions for weight management, the authors concluded that such interventions may prevent further weight gain and in some cases may result in weight loss (Loh et al. 2006).

Centrally acting weight-loss drugs that have the potential to increase biogenic amine activity could theoretically exacerbate symptoms of psychosis in this population. However, anecdotal reports suggesting the utility of nizatidine, citmetadine, metformin, topiramate, sibutramine, and amantadine in the prevention or treatment of antipsychotic-associated obesity exist (Werneke et al. 2002) but have not been substantiated with well-controlled trials. Orlistat, the non–centrally acting weight-control drug, may theoretically have a role in helping patients with schizophrenia lose weight, although no clinical trials have been reported to date (A. I. Green et al. 2000). One case series (Hamoui et al. 2004) suggested that bariatric surgery was as effective in promoting weight loss in patients with schizophrenia as it is in other obese patients.

The differential propensity of the various agents to cause weight gain, and glucose and lipid dysregulation, should be taken into consideration when treating individuals at increased risk. Clinicians should employ monitoring, such as that recommended by the American Diabetes Association–American Psychiatric Association consensus panel (American Diabetes Association et al. 2004). Patients who develop glucose intolerance or diabetes may require treatment with hypoglycemic agents, and those with hyperlipidemia may require lipid-lowering agents in collaboration with an internist. Although to the best of our knowledge no studies of the long-term effects of these simple interventions in minimizing the overall morbidity of this patient population have been done, such interventions may be important in the lowering of long-term morbidity.

Cigarette Smoking

Reports indicate that up to approximately 90% of patients with schizophrenia smoke cigarettes, over three times the rate seen in the general population (S. Brown et al. 2000; Dalack et al. 1998; Meyer and Nasrallah 2003). Heavy cigarette smoking contributes to the risk of coronary heart disease, which accounts for over 50% of the mortality in patients with schizophrenia (Hennekens et al. 2005). Beyond health, tobacco use results in financial consequences, with some schizophrenia patients spending nearly a third of their disability income on cigarettes (Steinberg et al. 2004). It has been proposed that the high rates of smoking may relate to abnormalities in brain reward circuitry (including presynaptic nicotinic acetylcholine receptors within mesolimbic and mesocortical dopamine pathways) and self-medication of clinical symptoms and cognitive deficits (George and Vessicchio 2001; Knott et al. 2006; Ripoll et al. 2004; Sacco et al. 2005). Indeed, such hypotheses and observations may provide insight into the neurobiology of schizophrenia and targets for treatment of both schizophrenia and nicotine addiction (Meyer and Nasrallah 2003).

Treatment of nicotine addiction in the schizophrenia population has been met with limited success and appears to be even more difficult for this patient population compared with both the general and other psychiatric populations (Covey et al. 1994). Nonetheless, evidence suggests that a multimodality approach, which integrates motivation-based treatment, addiction treatment, and tobacco dependence treatment into mental health settings, may be beneficial (Ziedonis et al. 2003). Group therapy, when combined with a nicotine patch, may help reduce smoking (George et al. 2000), and

bupropion in combination with psychotherapy may reduce tobacco use in patients with schizophrenia (Evins et al. 2005; Weiner et al. 2001). Additionally, in a case series of patients previously unable to quit smoking despite tobacco dependence treatment, use of nicotine nasal spray was associated with substantial reduction in or abstinence from smoking in 9 of 12 patients (J. M. Williams et al. 2004). Interestingly, whereas typical antipsychotic medications may be associated with an increase in smoking (McEvoy et al. 1995a), treatment with clozapine may lead to a decrease (George et al. 1995; McEvoy et al. 1995b). Finally, some other atypical antipsychotic medications may facilitate the ability of the nicotine patch itself to decrease smoking (George et al. 2000).

HIV and Hepatitis Risks

Patients with schizophrenia, especially those with substance abuse, are at high risk for HIV and hepatitis B and C (Cournos and Bakalar 1996; Meyer and Nasrallah 2003; Rosenberg et al. 2001). A cross-sectional Medicaid claims analysis found that patients with schizophrenia spectrum illnesses were 1.5 times as likely to have a diagnosis of HIV compared to recipients without a diagnosis of serious mental illness (Blank et al. 2002). Additionally, recent retrospective evaluations of both large Department of Veterans Affairs and civilian populations indicate that patients with schizophrenia or severe mental illness have rates of hepatitis C virus (HCV) seropositivity of approximately 20% (Huckans et al. 2006; Meyer and Nasrallah 2003) and that the rate of HCV infection in patients with schizophrenia is 11 times higher than found in the general population (Osher et al. 2003; Rosenberg et al. 2001). Risk factors such as unsafe sexual practices, combined with multiple partners, place patients with schizophrenia at heightened risk for sexually transmitted diseases (Sewell 1996). Patients should be asked about their sexual practices and, when indicated, tested for HIV and hepatitis. Discussions that provide education about safe sex are important. For those schizophrenic patients with HIV/AIDS or hepatitis, a close collaboration with a medical specialist is essential, as treatment may be complicated by poor adherence, neuropsychiatric consequences of antiviral therapies (e.g., interferon), and drug–drug and drug–disease interactions.

Extrapyramidal Side Effects

The term *extrapyramidal side effects* (EPS) describes a spectrum of adverse reactions, including akathisia, parkinsonism, and acute dystonia, induced in some patients by antipsychotic medications. Parkinsonism and acute dystonia are associated with the degree of dopamine D_2 receptor occupancy in the striatum (Kapur and Remington 1996). Thus, high-potency first-generation antipsychotics, such as haloperidol, have the greatest propensity (especially at high doses) to cause these side effects, but many second-generation agents, such as risperidone, olanzapine, and ziprasidone, also may cause EPS in a dose-dependent manner. The CATIE study found that the rate of drug discontinuation due to reported EPS was 8% in the patient group treated with the typical antipsychotic perphenazine, with rates of 4% for ziprasidone, 3% for risperidone and quetiapine, and 2% for olanzapine (Lieberman et al. 2005). Among the second-generation agents, quetiapine and clozapine do not appear to produce clinically significant parkinsonism or dystonia. In addition, aripiprazole has a low propensity to cause EPS (Ohlsen and Pilowsky 2005), although there are case reports of akathisia (Cohen et al. 2005) and parkinsonism (Cohen et al. 2005; Sharma and Sorrell 2006; Ziegenbein et al. 2006) occurring with this drug.

Akathisia, a disturbing sense of inner restlessness and the inability of the patient to stay still, is associated with seemingly purposeless movements (such as tapping or pacing) that may be noticeable to the examiner. The restlessness of akathisia may be misdiagnosed as an increase in psychosis, one that worsens when treated by higher doses of antipsychotic medication. Like other EPS, akathisia appears less likely to occur with second-generation agents (Glazer 2000b). Although lowering the dose of the antipsychotic is an obvious treatment for akathisia, addition of a β-blocker (e.g., propranolol) is often effective. Anticholinergic drugs and benzodiazepines are generally not that effective but can be tried in patients who fail to respond to β-blockers, and anticholinergics also may

be useful in patients with coexisting parkinsonism.

Parkinsonism (Osser 1999), characterized by tremor, rigidity, and bradykinesia, can occur early in treatment, usually within the initial weeks or months. Bradykinesia includes generalized slowing of movement and a mask-like face (with a loss of facial expression); it may be confused with depression or negative symptoms. One variant of parkinsonism, akinesia, can coexist with bradykinesia (but without tremor or rigidity) and may be associated with symptoms of apathy and fatigue. The "rabbit syndrome" (Casey 1999), occurring after months or years of antipsychotic drug treatment, is also a variant of parkinsonism and is characterized by a perioral and jaw tremor. As with other forms of EPS, the second-generation antipsychotics appear less likely to cause parkinsonism than the older agents (Glazer 2000b), although the rate of parkinsonism may be dose related with some of the newer agents. Anticholinergic medications are the treatment of choice and usually are effective. Lower doses of antipsychotics and a switch to an agent less likely to produce EPS also may be helpful.

Acute dystonia occurs most commonly during the week after initiation of antipsychotics or following an abrupt and rapid dose increase (Ayd 1961; Barnes and Spence 2000; Remington and Kapur 1996). Age is an important risk factor; dystonia occurs most commonly in children and young adults, especially in males. The dystonia may appear as torticollis, trismus, tongue protrusion, pharyngeal constriction, laryngospasm, blepharospasm, oculogyric crisis, or abnormal contractions of any part of the body. Clinically, in addition to the dystonic muscular contractions that may be immediately noticeable, the patient may complain of tongue thickening, throat tightening, and difficulty speaking or swallowing. Acute treatment with either an anticholinergic agent or an antihistamine is usually highly effective but may need to be repeated at intervals if acute dystonia recurs (before the dose of the anticholinergic is stabilized). Should respiratory difficulty develop, medications may need to be given parenterally.

Tardive Dyskinesia and Tardive Dystonia

Tardive dyskinesia, which is a syndrome of potentially irreversible involuntary movements, and tardive dystonia, which is characterized by sustained muscle contractions, can gradually emerge after a prolonged period of treatment with antipsychotic medications. Accumulating evidence suggests that the second-generation antipsychotics are less likely to cause these tardive syndromes than the first-generation drugs (Jeste et al. 1998; Kane et al. 1993; Marder et al. 2002; Margolese et al. 2005; Shirzadi and Ghaemi 2006; Tarsy and Baldessarini 2006; Tollefson et al. 1997). However, since many patients have had exposure to more than one second-generation agent, it is difficult to determine the risk associated with individual agents. It appears that compared with the first-generation agents, collectively the second-generation drugs carry one-fifth to one-twelfth the risk of causing tardive dyskinesia and tardive dystonia (Correll et al. 2004; Kane 2004; Leucht et al. 2003b; Margolese et al. 2005; Tarsy and Baldessarini 2006).

The most common form of tardive dyskinesia involves dyskinetic movements of the orofacial and buccolingual musculature, manifesting as grimacing, facial tics, lip smacking, chewing, and wormlike movements of the tongue. Involvement of the neck, axial, and extremity musculature also may occur in the form of choreoathetoid movements, which on rare occasions may involve laryngopharyngeal and respiratory muscles. Tardive dystonia may occur earlier in treatment than tardive dyskinesia and is characterized by slow, sustained twisting movements of the head, neck, trunk, and extremities; blepharospasm, torticollis, facial grimacing, back arching, and hyperextension and rotation of the limbs may also be seen (Simpson 2000).

Among the risk factors for tardive dyskinesia, age appears quite important; elderly individuals have an incidence five to six times higher than that in younger people (Kane 2004). Tardive dyskinesia occurs more frequently in older female patients (Jeste 2000; Saltz et al. 1991), whereas tardive dystonia is more common in younger patients and males. Other risk factors for tardive dyskinesia include mood

disorders (Keck et al. 2000), race/ethnicity (African American) (Keck et al. 2000), high doses of medication (Glazer 2000a, 2000c), previous evidence of parkinsonian side effects from antipsychotics (Keck et al. 2000), early onset of extrapyramidal syndromes (Kane 2004), and substance abuse (Miller et al. 2005).

Although no treatment has been proven to be effective for tardive dyskinesia, several management strategies may be clinically useful. Clinicians should screen patients taking antipsychotic medications on a regular basis. If tardive dyskinesia develops, switching from a first-generation to a second-generation drug may be helpful. For those patients who are taking a second-generation agent, a switch to another second-generation drug may be considered. Among the second-generation drugs, evidence suggests that clozapine may reduce symptoms of tardive dyskinesia (Glazer 2000a; Lieberman et al. 1991). Symptoms may also be suppressed, at least temporarily, by increasing the dosage of the antipsychotic medications that produce tardive dyskinesia; however, this strategy runs the risk of causing or worsening EPS and possibly increasing tardive dyskinesia over time. Patients with tardive dyskinesia who are taking anticholinergic medications should have these medications discontinued, because they can worsen tardive dyskinesia. Finally, the symptoms of tardive dystonia may be alleviated by reducing the dosages of the antipsychotics, by switching from first-generation to second-generation agents (including clozapine), by using anticholinergics, and/or by administering dopamine-depleting agents, such as reserpine or tetrabenazine (Simpson 2000).

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS), which occurs in about 1%–2% of patients receiving typical antipsychotic medication and is potentially fatal in up to 20% of the cases (without treatment), has been reported to occur during treatment with both the typical (Caroff and Mann 1993) and the atypical (Ananth et al. 2004; Hasan and Buckley 1998; Wirshing et al. 2000) antipsychotics. Several factors may increase risk, including intramuscular injections, rapid escalation of high doses of antipsychotic medication, dehydration, restraint use, and high temperatures. Catatonia and severe disorganization are clinical symptoms that may be associated with a high risk for NMS (Berardi et al. 2002). Symptoms of NMS include hyperpyrexia, altered consciousness, muscle rigidity and dystonia, autonomic nervous system dysfunction, and laboratory tests indicating elevated creatine phosphokinase, liver enzymes, and white blood cell count. Early detection and rapid treatment of this medical emergency are crucial and include discontinuation of the antipsychotic, treatment in a medical setting that can support vital functioning, and in some cases the use of a dopamine agonist such as bromocriptine or dantrolene, a muscle relaxant (Koppel 1998; Susman 2001).

Hyperprolactinemia

Antipsychotic medications—particularly typical agents, risperidone, and paliperidone—can produce an increase in serum prolactin levels (Dickson and Glazer 1999; Marder et al. 2004). Although early studies reported few negative consequences of long-term prolactin elevation (Meltzer 1985), this topic has received increased attention in recent years. It is well known that hyperprolactinemia secondary to medical disorders (e.g., pituitary tumor) can produce galactorrhea, hypogonadism (evidenced by sexual and menstrual dysfunction and diminished gonadal hormone levels), and osteoporosis, all of which have also been reported in patients with schizophrenia (Abraham et al. 1996; Ghadirian et al. 1982; Riecher-Rossler et al. 1994; Windgassen et al. 1996; Yazigi et al. 1997). Yet the relationships between antipsychotic-induced hyperprolactinemia and these conditions, perhaps with the exception of galactorrhea (Windgassen et al. 1996), remain unclear, with conflicting reports in the literature (Canuso et al. 2002; A. M. Costa et al. 2007; Hummer et al. 2005; Kinon et al. 2006; Kleinberg et al. 1999; O'Keane and Meaney 2005). Interestingly, several reports suggest that hypoestrogenism in schizophrenia occurs in women with and without hyperprolactinemia (Bergemann et al. 2005; Canuso et al. 2002; T. J. Huber et al. 2004). Thus, while prolactin-related hypogonadism may contribute to the increased risk of these conditions, it appears that patients with schizophrenia

may be at inherent risk for hypogonadism. The important question of whether drug-induced hyperprolactinemia increases long-term breast cancer risk has also been raised. Although a large claims database analysis found a 16% increase in the risk of breast cancer in women exposed to dopamine antagonists, the authors concluded that these results are preliminary and potentially confounded and should not necessarily lead to changes in treatment strategies (Wang et al. 2002). Finally, a recent retrospective review of pharmacovigilance data suggested that treatment with potent D_2 receptor antagonists, such as risperidone, may be associated with increased risk for pituitary tumors (Szarfman et al. 2006). Prospective studies are needed to confirm this association.

Clinicians should inquire about possible adverse effects of hyperprolactinemia and aim to diminish them. If a patient is symptomatic, prolactin levels should be obtained and medical causes of hyperprolactinemia ruled out. Prolactin elevation associated with galactorrhea, or sexual and menstrual dysfunction, may be minimized by dosage reduction or by a medication change to an atypical antipsychotic with less prolactin-elevating potential (Canuso et al. 1998; Dickson and Glazer 1999). Because patients with schizophrenia generally require chronic treatment with antipsychotics, those who have had prolonged hyperprolactinemia may be at an increased risk for osteoporosis (Abraham et al. 1996) and may be appropriate candidates for screening with bone densitometry. Female patients should have routine mammography in accordance with the screening guidelines set forth for all women.

PSYCHIATRIC CONDITIONS COMORBID WITH SCHIZOPHRENIA AND THEIR TREATMENT

Substance-Related Disorders

Nearly one-half of the patients with schizophrenia are reported to have a lifetime history of an alcohol or a substance use disorder, compared with 16% of the general population (Regier et al. 1990). Alcohol is the most commonly abused substance in chronically ill patients, followed by cannabis and cocaine (Selzer and Lieberman 1993; Sevy et al. 1990); first-episode patients appear more likely to abuse cannabis over other substances (Rolfe et al. 1999). As in the general population, men with schizophrenia are more likely to abuse substances than are women (Mueser et al. 1995).

The use of alcohol, marijuana, cocaine, and other substances can cause serious problems for patients with schizophrenia. Comorbid substance use has a deleterious effect on both physical health and the long-term course of schizophrenia itself (Grech et al. 1999); use of even small amounts can produce negative effects (D'Souza et al. 2005; Drake et al. 2001). Patients with schizophrenia and substance abuse are at increased risk for infectious diseases such as HIV, hepatitis B, and hepatitis C (Rosenberg et al. 2001); in addition, alcohol and substance use is associated with clinical worsening, poor functioning, and an increased rate of hospitalizations and homelessness (Dixon et al. 1990; Drake and Mueser 1996; Hurlburt et al. 1996a; Negrete et al. 1986; Soni and Brownlee 1991). In some studies, more than 50% of the first-episode patients have been reported to have cannabis use disorder (Rolfe et al. 1999), often complicating the diagnosis of a psychotic disorder (Addington 1999). Comorbid alcohol and substance use often has an overwhelmingly negative effect on the ability of patients to function at their highest possible level (Dickey and Azeni 1996).

Given the negative consequences of substance abuse in these patients, investigators have tried to understand the basis of such use. One theory, the "self-medication" hypothesis, suggests that alcohol and substances of abuse help to decrease negative symptoms of schizophrenia and the EPS produced by antipsychotic medications (Glynn and Sussman 1990; Khantzian 1985; Siris 1990). However, although alcohol and substances of abuse may in fact transiently alleviate negative symptoms and EPS, our group has suggested that the existence of negative symptoms or EPS of antipsychotics may not be causally related to the substance use (A. I. Green et al. 1999). Some studies indicate that patients with few negative symptoms may actually use substances more than do those with more negative symptoms (Buchanan et al. 1997; Lysaker et al. 1994). Also, first-episode patients, who have

not yet been exposed to antipsychotic medication and who therefore could not have EPS, are quite likely to use alcohol or substances (A. I. Green et al. 2004).

We (A. I. Green et al. 1999; Roth et al. 2005) have introduced a neurobiological formulation, based on animal studies (Svensson et al. 1995), suggesting that a deficiency in the dopamine-mediated mesocorticolimbic brain reward circuit of patients with schizophrenia may underlie the use of alcohol and substances in these patients. This formulation posits that alcohol and substances of abuse may ameliorate this deficiency by improving the "signal detection" capability of dopamine-rich systems, by which they reduce negative symptoms and EPS while enhancing the reward system (Fadda et al. 1989; Goeders and Smith 1986; A. I. Green et al. 1999). A related neurobiological formulation also has been proposed by Chambers et al. (2001).

Although obtaining information from patients about the use of substances of abuse should be a standard part of a medical history, alcohol or substance abuse is often underrecognized and undertreated in mental health settings (Ananth et al. 1989). Because patients often deny the use of alcohol and drugs, clinicians also should pursue collateral reports from family members, case managers, and others involved in the delivery of services to patients. Unfortunately, the traditional separation of mental health and substance abuse services compounds the problems of detection. Patients with schizophrenia and a comorbid alcohol or substance use disorder require specialized treatment for both disorders (Bellack and DiClemente 1999), optimally in programs that provide integrated mental health and substance abuse treatment, as well as medication management (Drake and Mueser 2001; Minkoff 1989; Osher and Kofoed 1989). Drake and Mueser (2001) reported that the treatment of comorbid substance abuse requires long-term comprehensive services (Osher and Kofoed 1989), including individual treatment planning tailored to the patient's ability to engage in treatment and assertive outreach (Drake and Mueser 2000; Ziedonis et al. 2000), with interventions within the social support system. The specific integrated interventions for substance abuse in patients with schizophrenia with the most evidence are group counseling with cognitive-behavioral and motivational components (Bellack et al. 2006; Weiss et al. 2007), contingency management (Drebing et al. 2005; Ries et al. 2004), and, for patients who do not respond to less intensive interventions, long-term residential programs (Brunette et al. 2004).

Although there is no agreed-upon pharmacological treatment approach for patients with schizophrenia and comorbid alcohol or substance use disorders (A. I. Green et al. 2007, 2008; Wilkins 1997), some investigators have been interested in the potential role of atypical antipsychotics in these patients. The atypical antipsychotic that has been studied most in this population is clozapine. Three preliminary studies—a naturalistic study (Drake et al. 2000) and two retrospective studies (A. I. Green et al. 2003; Zimmet et al. 2000)—reported a large reduction in alcohol use in patients taking clozapine; evidence also was found for a reduction in cannabis and cocaine use. Two other studies (Buckley et al. 1999; Lee et al. 1998) also have reported this beneficial effect of clozapine in patients with schizophrenia and comorbid substance use disorder. Clozapine was also associated with reduced rates of relapse to substance abuse in patients who had been in remission (Brunette et al. 2006). Randomized trials of clozapine needed to confirm these preliminary studies are currently under way.

The data concerning the potential effect of the other atypical antipsychotics are even more preliminary. Reports on risperidone appear to be conflicted (Albanese 2000; A. I. Green et al. 2003), although a report by Smelson et al. (2000) found that cocaine-abusing schizophrenic patients treated with risperidone experienced less craving, had fewer relapses, and remained in treatment longer than did those treated with typical antipsychotics. Recently, Rubio et al. (2006) reported that the new LAI form of risperidone was more effective in improving substance abuse than a depot form of the typical agent zuclopenthixol (which is not available in the United States), but the difference was small and probably not clinically significant. However, a report of data from a large Veterans Administration treatment group showed no advantage for either risperidone or olanzapine compared with typical

antipsychotics on clinical substance abuse measures (Petrakis et al. 2006). Two other open prospective studies of olanzapine treatment noted improvements in substance use, but one of them (Noordsy et al. 2001), which might have been limited by statistical power, did not find significant advantages of olanzapine over typical antipsychotic treatment (Littrell et al. 2001; Noordsy et al. 2001). Two randomized trials of olanzapine's impact on cocaine craving and use compared to typical antipsychotics also reported conflicting results (Sayers et al. 2005; Smelson et al. 2006). Preliminary research on quetiapine and aripiprazole is promising. Two open studies of quetiapine (E. S. Brown et al. 2003; Potvin et al. 2006) and of aripiprazole (Beresford et al. 2005; E. S. Brown et al. 2005) suggest that these medications may be helpful for alcohol and/or cocaine use disorders in patients with schizophrenia. No research has assessed the impact of ziprasidone.

Other possible pharmacological options for treatment of alcohol or substance use disorder in schizophrenia include the following: 1) disulfiram (Kofoed et al. 1986), which one randomized, placebo-controlled trial (Petrakis et al. 2005) and one open trial (Mueser et al. 2003) suggest is effective for alcohol dependence in patients with schizophrenia but requires monitoring (Kofoed et al. 1986); 2) naltrexone, which was found to decrease alcohol use among patients with schizophrenia in two randomized, placebo-controlled trials (Petrakis et al. 2004, 2005); 3) the tricyclic antidepressants desipramine or imipramine for the treatment of comorbid cocaine disorders (Siris et al. 1993; Ziedonis et al. 1992); and 4) bupropion for the treatment of nicotine dependence in these patients (George et al. 2002). Acamprosate, although shown to be effective for alcohol dependence in placebo-controlled trials, has yet to be studied in patients with schizophrenia. Clearly, more studies need to be undertaken to develop optimal pharmacological strategies for the treatment of these comorbid disorders.

Depression

Schizophrenia is often associated with depressive states, from dysphoria to major depression. The Epidemiologic Catchment Area study suggests that those with schizophrenia have a 14-fold greater risk of depression than the general population (Fenton 2001). At various times, depression has been viewed as an aspect of schizophrenia (McGlashan and Carpenter 1976; Sax et al. 1996), as a response to psychosis (McGlashan and Carpenter 1976; Sax et al. 1996), or as a state occurring after the cessation of frank psychotic symptoms (Birchwood et al. 2000). Depressive symptoms can occur throughout the course of schizophrenia, including in first-episode patients (Hafner et al. 2005; Koreen et al. 1993), but in chronically ill patients in particular, these symptoms appear to be associated with risk of relapse (Mandel et al. 1982) and suicide (Drake et al. 1986).

Assessing patients with schizophrenia for the presence of depression requires knowledge of the types of depressive states in patients with schizophrenia and the conditions, such as negative symptoms and EPS, that can be confused with depression. In detecting depression, the presence of a core depressed mood and related neurovegetative symptoms should be distinguished from flatness of affect and anhedonia (McGlashan and Carpenter 1976). Depression occurring during an exacerbation of psychosis may remit with treatment of the psychosis (Birchwood et al. 2000; Koreen et al. 1993; Tollefson et al. 1999). However, postpsychotic depression classically develops after the resolution or improvement of psychotic symptoms, particularly in first-episode patients (Birchwood et al. 2000; Koreen et al. 1993). Moreover, dysphoria and demoralization frequently occur in patients with schizophrenia (Iqbal et al. 2000; Siris 2000a), as patients struggle with illness-related disability, but these symptoms may not be associated with the classical neurovegetative symptoms of depression (Bartels and Drake 1988).

Treatment of depression in patients with schizophrenia may include both psychopharmacological and psychosocial components (Siris 2000b). Because depression may presage an increase in psychosis, the adequacy of pharmacological treatment of psychotic symptoms should be assessed. Treatment of depression in acute psychosis may be accomplished through the use of antipsychotic medication

alone, especially the atypical antipsychotics (Banov et al. 1994; Levinson et al. 1999; Marder et al. 1997; Tollefson et al. 1998). However, major depression developing after the remission of psychosis often requires more specific intervention, such as treatment with combinations of antipsychotics and antidepressants or mood stabilizers (Levinson et al. 1999). Postpsychotic depression may benefit from the addition of tricyclic antidepressants or serotonin reuptake inhibitors to the antipsychotic medication (Hogarty et al. 1995; Kirli and Caliskan 1998; Siris et al. 1987). However, demoralization and dysphoria do not appear to be responsive to antidepressants (Iqbal et al. 2000; Levinson et al. 1999); rather, appropriate psychosocial interventions (e.g., stress management, job training, cognitive therapy, support) may be most helpful (Siris 2000b).

Suicide

Suicide is the leading cause of premature death in patients with schizophrenia, who have a 10% lifetime risk of suicide. Nearly 50% of the patients with schizophrenia attempt suicide during their lifetime (Black et al. 1985; Tsuang et al. 1999a). The risk of suicide is as high in patients with schizophrenia as in patients with mood disorder and is 10-fold higher than in the general population (Baxter and Appleby 1999). Several factors are associated with an increased risk of suicide in patients with schizophrenia: depression and the diagnosis of schizoaffective disorder (Harkavy-Friedman et al. 2004; Radomsky et al. 1999), social isolation (Drake et al. 1986; G. Goldstein et al. 2006; Potkin et al. 2003), and feelings of hopelessness and disappointment over failure to meet high self-expectations (Kim et al. 2003; Westermeyer et al. 1991). Patients with a higher level of insight and awareness of their illness may be at increased risk (Amador et al. 1996; Bourgeois et al. 2004; Crumlish et al. 2005), as may patients with a poor level of functioning (Kaplan and Harrow 1996).

A history of suicide attempts is one of the strongest predictors of suicide in patients with schizophrenia (Rossau and Mortensen 1997; Roy 1982a). In a large 2-year prospective study of 980 schizophrenia and schizoaffective disorder patients at high risk for suicide, multivariate analysis found the number of lifetime suicide attempts, number of hospitalizations to prevent suicide in the previous 3 years, history of alcohol or substance abuse, baseline anxiety scale score, and severity of parkinsonism to be the strongest predictors of suicide (Potkin et al. 2003). Moreover, a recent meta-analysis of 29 case–control and cohort studies indicated that suicide risk factors included previous depressive disorders, drug abuse, agitation or motor restlessness, fear of mental disintegration, poor adherence to treatment, and recent loss (Hawton et al. 2005).

Gender also appears to be a risk factor (Rossau and Mortensen 1997); men with schizophrenia commit suicide at an earlier age than do women with schizophrenia (Roy 1982a). An increased risk of suicide is present in the early phase of the illness (Drake et al. 1985; Kuo et al. 2005; Ran et al. 2005), especially in those patients with an earlier age at onset of schizophrenia (Gupta et al. 1998). The risk of suicide appears to peak immediately after admission and shortly after discharge (Qin and Nordentoft 2005; Rossau and Mortensen 1997), especially in patients who are hospitalized for short periods (Qin and Nordentoft 2005) and in those who return to a socially isolated environment (Drake et al. 1986). Patients in an active phase of the illness (Heila et al. 1997) or with positive symptoms (Kelly et al. 2004) may be at risk, especially if they have prominent symptoms of suspiciousness and delusions (Fenton et al. 1997).

A national clinical survey conducted in Great Britain, based on a 4-year (1996–2000) sample of people who died by suicide, found that the deaths of schizophrenia patients were characterized by more violent methods: they were more likely than others to be young, male, unmarried, and from an ethnic minority, with high rates of unemployment (Hunt et al. 2006). Moreover, rates of previous violence and drug abuse were high, and suicide victims were proportionally more likely to be inpatients at the time of death and to have been noncompliant with medication (Hunt et al. 2006). In another study (Roy 1982b), half of all patients who committed suicide had been seen in the week prior, and in another study (Heila et al. 1997), between 49% and 96% of the patients had been seen within 3

months of the suicide.

The treating clinician should regularly evaluate the patient's condition, assess for suicide risk factors, and aim to enhance protective factors such as social support and positive coping skills (Montross et al. 2005). Patients who present with suicidal thoughts or behavior require close follow-up and intensive outreach. For the isolated or newly diagnosed patient, a clear aftercare plan (often in a day treatment center) should be in place before discharge from the hospital (Drake et al. 1986; Harkavy-Friedman and Nelson 1997). Improved ward safety, effective substance abuse treatment, affective symptom control, and ensured medication adherence are all measures that may prevent suicide (Hawton et al. 2005; Hunt et al. 2006). Additionally, evidence suggests that community programs for early detection of schizophrenia may reduce suicidality risk (Melle et al. 2006).

Psychopharmacological treatment plays a crucial role in the prevention of suicide. In one study, more than half of the patients who committed suicide were either medication noncompliant or prescribed inadequate doses of antipsychotics, and 23% of the sample were thought to be nonresponsive to treatment (Heila et al. 1999). Moreover, a landmark study of nearly 1,000 patients with schizophrenia and schizoaffective disorder who were at risk for suicide (but who were not necessarily classically treatment resistant) indicated that treatment with clozapine was more likely to decrease suicidality than was treatment with olanzapine (Meltzer et al. 2003).

Obsessive-Compulsive Symptoms

Obsessive-compulsive symptoms are seen in 8.8%–30% of patients with schizophrenia (I. Berman et al. 1995a; Byerly et al. 2005; Cassano et al. 1998; Ongur and Goff 2005). Although obsessive-compulsive symptoms may be difficult to distinguish from delusions (Eisen et al. 1997), they are important to identify because they may indicate a poor prognosis, yet they may be responsive to specialized treatment regimens. Most studies have indicated that obsessive-compulsive symptoms are associated with unfavorable outcomes—with increased social isolation, longer hospitalizations, greater psychopathology, and poor treatment response (Fenton and McGlashan 1986; Hwang et al. 2000; Ongur and Goff 2005). By contrast, a more recent study (N = 58) suggested that the presence of obsessive-compulsive symptoms does not impact clinical outcomes (Byerly et al. 2005). The obsessive-compulsive symptoms in schizophrenia are similar to those found in obsessive-compulsive disorder (Tibbo et al. 2000), although they may not be ego-dystonic in patients with schizophrenia.

Treatment of obsessive-compulsive schizophrenia may require the use of a tricyclic antidepressant or a serotonin reuptake inhibitor with a typical antipsychotic (I. Berman et al. 1995b; Chang and Berman 1999; Poyurovsky et al. 2000). The data regarding the role of atypical agents in these patients are mixed (Fenton 2001). Some reports suggest that atypical antipsychotics may exacerbate obsessive-compulsive symptoms, whereas others suggest that they may be helpful (Baker et al. 1992, 1996; Kopala and Honer 1994; Morrison et al. 1998; Ongur and Goff 2005; Strous et al. 1999). Although the addition of a serotonin reuptake inhibitor to an atypical antipsychotic may decrease obsessive-compulsive symptoms in these patients (as the addition of a serotonin reuptake inhibitor to some typical agents does), the combined use of serotonin reuptake inhibitors with clozapine, especially, may require care because of the possible increase in blood levels of clozapine.

FUTURE DIRECTIONS

Novel Pharmacotherapeutic Treatment

Although all existing antipsychotic medications have effects on the dopamine system, other neurotransmitter systems are increasingly being recognized as possible therapeutic targets. For instance, the glutamate hypothesis of schizophrenia (Coyle 1996; Goff and Coyle 2001; Javitt and Zukin 1991; Olney and Farber 1995) suggests that modulation of glutamatergic activity could be a potential target for pharmacological treatment of schizophrenia. The glutamate hypothesis is, to a

large extent, derived from the observation that treatment of healthy subjects with *N*-methyl-D-aspartate (NMDA) antagonists, such as ketamine and phencyclidine (PCP), produces symptoms reminiscent of schizophrenia (Adler et al. 1998; Newcomer et al. 1999). Most important, in addition to the psychotic symptoms, which can be induced by a variety of central nervous system stimulants or hallucinogens, NMDA antagonists uniquely produce many of the cognitive deficits associated with schizophrenia (Krystal et al. 1994) and symptoms that resemble the negative symptoms of the illness (Abi-Saab et al. 2001). Thus, it would follow that drugs that enhance NMDA receptor function might be beneficial in the treatment of negative symptoms of schizophrenia (Javitt 2006; Javitt and Coyle 2004).

Because of the possible risks of neurotoxicity as a result of direct stimulation of NMDA receptors, drugs that indirectly enhance NMDA neurotransmission by modulating other binding sites on the NMDA receptor complex have been studied. For example, D-cycloserine (a partial agonist) (Goff et al. 1999), D-serine (Tsai et al. 1998), D-alanine (Tsai et al. 2006), glycine (Heresco-Levy et al. 1996a, 1996b; Javitt et al. 2001), agonists of the glycine binding site (located adjacent to the NMDA ion channel), and sarcosine (a glycine transporter-1 inhibitor) (Tsai et al. 2004) have been shown to have therapeutic potential. Preliminary data are quite promising, in that all of these agents appear to be effective in improving negative symptoms of schizophrenia, although their effects on positive symptoms, if any, tend to be very modest (Goff and Coyle 2001; Tsai et al. 1998), and it appears that they may not be effective in patients treated with clozapine (Goff et al. 1996; Potkin et al. 1999); but see Javitt et al. 2001).

Non-NMDA glutamate receptors may also be potential targets for treatment. For example, a recent preliminary study demonstrated that a selective agonist of metabotropic glutamate 2/3 (mGlu2/3) receptors, used as monotherapy, was efficacious in reducing both positive and negative symptoms in 196 patients with schizophrenia (Patil et al. 2007). MGlu2/3 agonists, which blunt the effects of PCP in animals, are thought to work in part by modulating glutamate release (Patil et al. 2007). This study suggests that agents that do not directly block dopamine receptors may have therapeutic potential in schizophrenia.

Another novel approach to the treatment of schizophrenia is the development of drugs that act as partial dopamine agonists. These drugs bind to dopamine receptors, including the presynaptic autoreceptors, with high affinity but with variable intrinsic activity, depending on the activity level of the target system (Tamminga 2002). Because of this, they exert a wide range of modulatory effects on the dopaminergic system. The first FDA-approved drug with this mechanism is aripiprazole.

Given the increasing evidence suggesting that neurocognitive deficits are pervasive in patients with schizophrenia and that they are important determinants of long-term functional outcome, there has been considerable interest in developing compounds that target these deficits. Drugs that may be effective, at least in theory, in the treatment of neurocognitive deficits include muscarinic agonists, alpha 7 nicotinic receptor agonists (Martin et al. 2007), ampakines (agonists of the AMPA [amino-3-hydroxy-5-methyl-4-isoxazole propionic acid] class of glutamate receptors) (Goff and Coyle 2001), class I metabotropic glutamate receptor agonists (Moghaddam 2004), dopamine D_1 receptor agonists (G. V. Williams and Castner 2006), and alpha 2 γ-aminobutyric acid (GABA) type A ($GABA_A$) receptor agonists (D. A. Lewis and Gonzalez-Burgos 2006). Although clinical experience with these drugs is quite limited, there are ongoing clinical trials to test the possible efficacy of at least some of these compounds.

Early Intervention and Prevention of Schizophrenia

As emphasized earlier in this chapter, some investigators have suggested that early detection and treatment of first-episode psychosis may improve the long-term prognosis of schizophrenia. In recent years, there have even been attempts to identify individuals who are in the prodromal phase of

schizophrenia but have not yet developed psychosis (Yung and McGorry 1996b), with the notion that intervention, including psychopharmacological treatment, during this period of the illness may be able to prevent the onset of full-blown psychosis (McGorry et al. 2002). However, as has been discussed in this chapter, many of the prodromal symptoms, among which depression and anxiety are common manifestations, are not specific to schizophrenia and are not uncommonly observed in otherwise healthy adolescents (McGorry et al. 1995). The issue of misidentification of individuals who are not at risk for psychosis must be considered. The current challenge is to establish the predictive validity of specific traits or prodromal symptoms of the diagnosis or recognition of the prodrome as a syndrome. However, even if these individuals can be reliably identified, the modes of treatment, including the specific classes of medications, that may be most effective in preventing the onset of psychosis are at present virtually unknown (Cannon et al. 2007; McGlashan et al. 2007).

Another concept that may help clarify prodrome is the notion of schizotaxia, which was originally put forward by Meehl (1962, 1989) and reformulated by Faraone et al. (2001) to describe a constellation of negative symptoms and neuropsychological deficits present in 20%–50% of the first-degree relatives of patients with schizophrenia. Preliminary findings from treatment of six such relatives meeting criteria for schizotaxia with low-dose risperidone (up to 2 mg) for 6 weeks suggested that this treatment may improve the deficits associated with this condition (Tsuang et al. 1999b). If the validity of schizotaxia as a "preschizophrenic" trait could be established (Tsuang et al. 2000), it would be important to determine whether treatment of schizotaxia in individuals with prodromal symptoms could actually be associated with a decrease in the incidence of schizophrenia.

Chapter 56. Treatment of Anxiety Disorders

TREATMENT OF ANXIETY DISORDERS: INTRODUCTION

Over the past decade and a half, there has been substantial progress in our understanding of the anxiety disorders. Particularly fruitful has been the search to develop new treatments for the six major anxiety disorders: obsessive-compulsive disorder (OCD), panic disorder, social phobia (social anxiety disorder), specific phobia, generalized anxiety disorder (GAD), and posttraumatic stress disorder (PTSD). In this chapter, we review the main findings from double-blind, and some open-label, trials in each disorder. Both short-term and continuation/maintenance treatment studies are included.

OBSESSIVE-COMPULSIVE DISORDER

When Kierkegaard wrote that "no grand inquisitor has in readiness such terrible tortures as has anxiety, which never lets him escape," he may well have been thinking of OCD, one of the few conditions that has the capacity to produce a lifetime of psychological torture. Before the existence of serotonin reuptake–inhibiting drugs, especially clomipramine, and selective serotonin reuptake inhibitors (SSRIs), biological treatments generally had little effect, producing mild palliation at best.

According to the Epidemiologic Catchment Area study (Myers et al. 1984; Robins et al. 1984), OCD carries a lifetime prevalence of 2.5% in the United States and 6-month and 1-month prevalence rates of 1.5% and 1.3%, respectively, although a more recent analysis from the National Comorbidity Survey Replication (NCS-R) suggested slightly lower rates of 1.6% and 1.0% for the lifetime and 12-month prevalence of OCD, respectively (Kessler et al. 2005a, 2005b). Its economic toll is also substantial (Hollander et al. 1997). OCD has been recognized as the tenth leading cause of disability worldwide (Murray and Lopez 1996). Treatment can be grouped broadly into psychosocial and psychopharmacological approaches, the latter being our focus here. First, we present information on monotherapy with serotonin reuptake–inhibiting drugs, followed by management of partial responders or nonresponders, and we conclude with comments on less frequently used treatments.

The chief rating scale for treatment studies of OCD remains the Yale-Brown Obsessive Compulsive Scale (Y-BOCS; Goodman et al. 1989), a 10-item observer-rated measure. Self-ratings are of less importance in the OCD literature and have traditionally received little weight.

Monotherapy

In 1967, Fernandez-Cordoba and Lopez-Ibor reported beneficial effects of the nonselective serotonin reuptake inhibitor (SRI) tricyclic antidepressant (TCA) clomipramine in treating OCD. Following this important insight, a series of placebo-controlled studies were completed in the late 1980s and the early 1990s, leading eventually to the first approved treatment of OCD in the United States and other countries (Clomipramine Collaborative Study Group 1991). Clomipramine differs from other tricyclic drugs in that it has a particularly potent serotonin reuptake–inhibiting effect. The drug is not selective for serotonin, however, in that its demethylated metabolite is a norepinephrine reuptake inhibitor. The anti-OCD effect of clomipramine correlates with the plasma level of the parent drug, which is an SRI, suggesting that reuptake inhibition of serotonin is the critical factor underlying the drug's benefit. Moreover, some studies have shown lack of effect for selective norepinephrine reuptake–inhibiting drugs, such as nortriptyline and desipramine, in OCD (Leonard et al. 1988; Thoren et al. 1980). An

interesting aspect of the pharmacokinetics of clomipramine is the ability of fluvoxamine to inhibit its demethylation, thereby increasing the amount of clomipramine relative to desmethylclomipramine, which can produce a potentiating effect in partial responders.

In the influential Clomipramine Collaborative Study Group (1991) trial, the Y-BOCS score was reduced by about 40% in patients taking the drug as compared with 5% in patients receiving placebo, bearing out findings by Mavissakalian et al. (1990) that OCD has a remarkably low placebo response rate. At one point, it was thought that clomipramine may have a larger effect size than SSRIs in the treatment of OCD (Greist et al. 1995b), but subsequently this finding has been interpreted as more likely to have been due to sampling differences between studies. In general, it is held that clomipramine and SSRI drugs are equivalent in the treatment of OCD (Koran et al. 1996). Nonetheless, clomipramine still may be a drug to consider in SSRI nonresponders. For the most part, in view of its greater side effects and risks, as well as dose-related risks of seizures, clomipramine would be regarded as a second-line treatment.

Today, SSRIs are considered first-line treatments for OCD, particularly the SSRIs fluvoxamine, fluoxetine, sertraline, and paroxetine, all of which have a U.S. Food and Drug Administration (FDA) indication for the treatment of OCD (Greist et al. 1995a, 1995b; Tollefson et al. 1994). Clomipramine, fluvoxamine, fluoxetine, and sertraline also have been shown to be effective in treating OCD in children, with an indication for treatment in such patients (Flament et al. 1985; Liebowitz et al. 2002; March et al. 1998; Riddle et al. 2001). Escitalopram is also efficacious in OCD at a daily dose of 20 mg on all main measures of efficacy, while 10 mg of escitalopram and 40 mg of paroxetine were superior to placebo on some measures but took longer to work (D. J. Stein et al. 2007).

Paroxetine and fluoxetine appear to be more effective at higher doses, whereas no clear relation between dose and effect was seen with sertraline, although a paradoxical finding of lesser efficacy at 100 mg/day was most likely an artifact. The results for escitalopram suggest that possibly a higher does of 20 mg is preferred, although 10 mg is somewhat effective. Recent results (Ninan et al. 2006) suggest additional benefit for increasing the dosage of sertraline up to 400 mg/day in nonresponders. Thus, when an SSRI drug is to be used in the treatment of OCD, not only may it need to be given in higher doses, but also it may take a longer time to work effectively. Most people believe that treatment should be long term to reduce the chance of relapse (Pato et al. 1990), although the dosage might be lowered without loss of benefit (Ravizza et al. 1996).

Long-Term Treatment and Relapse Prevention

Long-term pharmacological treatments of OCD have suggested sustained response of an effective medication beyond the acute treatment phase. In addition, clomipramine, paroxetine, sertraline, and most recently, escitalopram all have been shown to be more effective than placebo in preventing relapse in OCD (Fineberg et al. 2005, 2007). SSRIs appear to be well tolerated in these studies.

Augmentation, Combination, and Other Strategies

Up to 60% of individuals with OCD show a response to SSRIs according to a conventional and conservative criterion, full remission is rare, and response is often no more than partial. Relapse can occur even while patients continue taking an SSRI, and comorbidity is often a complicating factor in managing the disorder. The following augmentation, combination, and other novel strategies have been reported as offering benefit:

- Combining fluvoxamine with clomipramine (Szegedi et al. 1996) and the intravenous use of clomipramine as monotherapy (Fallon et al. 1992; Koran et al. 1997) are both approaches to consider in individuals who have shown a partial response to clomipramine. The rationale for combining fluvoxamine with clomipramine was explained in the previous section, but some caution is in order given the possibility of increased side effects and risk of seizure. Monitoring of plasma levels and electrocardiograms is important with this

combination. The use of intravenous clomipramine derives from the fact that first-pass metabolism is avoided, and there is some suggestion that side effects are less severe.

- The benzodiazepine clonazepam has been added to clomipramine with mixed benefits (Pigott et al. 1992) and to sertraline with no added benefit (Crockett et al. 1999). Each of these findings was based on a double-blind, placebo-controlled trial.
- Patients with OCD refractory to SRI treatments may benefit from additional antipsychotic augmentation. A meta-analysis of double-blind, randomized trials demonstrated significant benefits of haloperidol and risperidone over placebo augmentation for OCD patients who failed to show treatment response after an adequate trial of SRI, whereas evidence for the efficacy of olanzapine and quetiapine is less conclusive (Bloch et al. 2006). Despite the fact that this approach appeared to benefit only a limited number of subjects (although it was more beneficial among subjects who suffered from comorbid tic disorders), any increased chance of improvement is worth striving for.
- Greist and Jefferson (1998) have reported four studies in which SSRI and behavior therapy approaches were compared and/or combined. Three of these studies gave some modest support to the idea that combined treatment produces an enhanced effect. Also, rates of relapse after discontinuing behavior therapy are considerably lower than those after discontinuing drug therapy. Other studies of SRI and cognitive-behavioral therapy (CBT) using exposure and ritual prevention techniques have yielded inconsistent results as to the benefits of combining drug and CBT over CBT alone (Cottraux et al. 1993; Foa et al. 2005).
- The addition of lithium, buspirone, desipramine, or gabapentin has produced very limited benefits in studies to date, although there may be occasional patients for whom such combinations are helpful.

Other Approaches

One report suggested that St. John's wort (*Hypericum perforatum*) produced some improvement after 12 weeks of treatment in 12 patients with OCD (Taylor and Kobak 2000). The promise of this early finding has been dampened by failure of the same group to establish efficacy for St. John's wort in a subsequent and adequately powered placebo-controlled study (Kobak et al. 2005).

A double-blind trial of intravenous clomipramine suggested greater benefit than oral loading (Koran et al. 1997). Inositol, a naturally occurring second-messenger precursor, led to greater improvement than placebo at a dosage of 18 g/day for 6 weeks (Fux et al. 1996).

Neurosurgical approaches, wherein either cingulotomy or anterior capsulotomy are carried out, can be helpful for refractory OCD. Between 25% and 30% of the subjects show marked improvement, and the side-effect burden of this procedure is small (Baer et al. 1995; Jenike et al. 1991). Limited but promising studies also suggested other potential approaches such as deep brain stimulation for severely treatment-refractory OCD patients (B. D. Greenberg et al. 2006; Nuttin et al. 1999).

CBT is well established for treating OCD, and evidence for efficacy is strong (e.g., Eddy et al. 2004; Foa et al. 2005). In most types of CBT for this disorder, exposure with response prevention is used. CBT is a first-choice option for OCD.

PANIC DISORDER

Panic disorder is a chronic and costly (P. E. Greenberg et al. 1999) condition that affects approximately 1%–3% of the population (Alonso et al. 2004; Kessler et al. 2005b). It often presents as a medical emergency and is associated with substantial comorbidity and increased suicidal risks (Roy-Byrne et al. 2000). Effective treatment results in reduced emergency department and laboratory resource utilization (Roy-Byrne et al. 2001).

Five core areas of the disorder require treatment: 1) full and limited symptom panic attacks, 2) anticipatory anxiety, 3) phobias related to panic, 4) general well-being, and 5) disability (Ballenger et al. 1998a). Treatment outcome can be comprehensively and succinctly measured with the Panic

Disorder Severity Scale (PDSS), which can be administered both as a clinician-rated and as a self-rated scale (Shear et al. 1997).The PDSS contains seven domains relevant to panic disorder and agoraphobia. Other widely used measures include the Sheehan Panic and Anticipatory Anxiety Scale (PAAS; Sheehan 1986) and the self-rated Marks-Matthews Fear Questionnaire (FQ; Marks and Matthews 1979). Ideally, as with all of the anxiety disorders, the desired endpoint is full remission. However, this is not always attainable.

The earliest groups of drugs to show robust efficacy relative to placebo were the TCAs and the monoamine oxidase inhibitors (MAOIs) (Mavissakalian and Perel 1989; Sheehan et al. 1980). However, even before any randomized clinical trials had been published to support the use of SSRI drugs, the experts who were convened for the International Psychopharmacology Algorithm Project (Jobson et al. 1995) indicated that their preferred first-line approach was to use an SSRI. The other main approach would be to use benzodiazepine drugs, such as alprazolam or clonazepam (Lydiard et al. 1992; Rosenbaum et al. 1997; Tesar et al. 1991). Initial drug selection, to be based on discussion between the patient and the physician, would take into account issues of prior response, proneness to abuse of medication, tolerability, safety, comorbidity, and presenting clinical picture (e.g., degree of agitation).

First-Line Drug Treatments

Selective Serotonin Reuptake Inhibitors

In 1995, Boyer reported that SSRI drugs were more effective than imipramine and alprazolam in treating panic disorder, although a recent meta-analysis by Otto et al. (2001) failed to confirm these findings. Evidence is now available in support of citalopram (Wade et al. 1997), escitalopram (Stahl et al. 2003), fluoxetine (Michelson et al. 1998, 2001), fluvoxamine (Asnis et al. 2001; Black et al. 1993), paroxetine (Ballenger et al. 1998b; Oehrberg et al. 1995; Sheehan et al. 2005), and sertraline (Londborg et al. 1998). In addition, clomipramine has been shown to have efficacy in panic disorder (Lecrubier et al. 1997). Fluoxetine, paroxetine, and sertraline have been approved by the FDA for treatment of panic disorder.

Although SSRI drugs are favored as first-line treatment, the following points need to be kept in mind. Patients with panic disorder are often extremely sensitive to activating effects of antidepressants and have poor tolerance of symptoms such as palpitations, sweating, and tremor. It is therefore not uncommon for them to quickly lose faith and discontinue treatment or even drop out without a full discussion having taken place. This problem can almost always be obviated, either by coprescribing a benzodiazepine or by starting with extremely low doses of an SSRI and gradually building up as tolerated. Also, perhaps of most importance is the availability of the physician and thorough and reassuring preparation of patients ahead of time. Other problems of SSRIs to be concerned about in panic disorder are those common to all other conditions for which SSRIs are used (e.g., problems associated with weight gain, sexual dysfunction, impairment of sleep, and potential drug–drug interactions). Discontinuation of treatment can be a significant concern in panic disorder. Besides the obvious issue of relapse, SSRIs, with the exception of fluoxetine, may sometimes produce troublesome discontinuation symptoms. Many of these symptoms mimic panic disorder itself and can be quite distressing. Gradual dosage reduction is usually recommended, along with adequate patient education and physician availability. Coping strategies, including behavior therapy (Otto et al. 1993), are an option. Switching to an SSRI such as fluoxetine also may be considered because this drug has a slow built-in taper. One also might consider using serotonin$_2$ (5-HT$_2$) or serotonin$_3$ (5-HT$_3$) receptor antagonists, such as mirtazapine, nefazodone, and ondansetron, to limit some of the symptoms that are mediated through these pathways (e.g., insomnia, agitation, gastrointestinal distress).

Benzodiazepines

In the late 1980s, alprazolam received an FDA indication for treatment of panic disorder, making it the first product so licensed. An important byproduct of this indication was raising general awareness of the condition as well as helping to differentiate panic disorder with agoraphobia from other kinds of anxiety. Several trials showed that alprazolam was more effective than placebo. These included the Cross-National Collaborative Panic Study (1992), wherein imipramine and alprazolam were both more effective than placebo. Lydiard et al. (1992) reported that alprazolam 2 mg/day was more effective than placebo, and benefit for alprazolam was shown in other trials. Efficacy for clonazepam was also demonstrated in panic disorder (Davidson and Moroz 1998; Rosenbaum et al. 1997; Tesar et al. 1991).

Although alprazolam has been widely used for panic disorder, it is now regarded more as a second-line treatment. Problems include the need for frequent administration, tendency to produce sedation at higher doses, abuse liability, and discontinuation-related distress. Lesser et al. (1992) showed that higher plasma levels (i.e., >70 ng/mL) were associated with greater likelihood of response as compared with lower levels (in the 20–40 ng/mL range). Thus, higher doses may have an advantage, particularly in managing phobic avoidance, but often at the price of more side effects or discontinuation difficulty. Comparable efficacy and tolerability have been demonstrated for the sustained-release formulation of alprazolam (Pecknold et al. 1994; Schweizer et al. 1993). Clonazepam, which is also FDA approved for panic disorder, has an advantage over alprazolam in that its half-life is considerably longer and the drug can be dosed once or twice a day. However, it shares the usual class effects of benzodiazepines and can produce sedation, depression, and discontinuation syndrome. A particular concern with benzodiazepines is their use in the elderly. The elderly are not only more prone to developing side effects, including sedation and falls that result in fractures and potential head injury, but also more likely to experience problems upon discontinuation of the drug. In a fixed-dose study, clonazepam 1 mg/day was more effective than placebo on nearly all major measures; however, clonazepam 0.5 mg/day was ineffective except on the Hamilton Anxiety Scale (Ham-A; Hamilton 1959). In general, escalating the dosage up to 4 mg/day did not provide greater benefit, suggesting that such higher dosages should be reserved for patients who are refractory to treatment at lower dosages. In the clonazepam studies, ratings of actual panic attacks tended to be the least likely to detect drug and placebo differences. As pointed out by Bandelow et al. (1995), overreliance on reduction of panic attacks as the principal outcome measure is an unsatisfactory marker of overall treatment benefit. Despite the almost universal unhappiness with this measure, it continues to be chosen as a primary outcome for regulatory studies.

One interesting and important finding to emerge from the studies of clonazepam in panic disorder is its substantial benefits on quality of life and work productivity. A broad-spectrum effect was noted on all five measures of mental health–related quality of life. During a 6-week clinical trial, patients moved from the seventh percentile for all adult Americans with regard to mental health component score (MCS) of the Short Form–36 (SF-36) to the seventeenth percentile. By contrast, the placebo group moved only from the eighth to the twelfth percentile during this time. With respect to work productivity, the difference between the effects of clonazepam and placebo during a 6-week treatment period amounted to an additional 6 hours of full productivity during a 40-hour workweek (Jacobs et al. 1997).

Other Pharmacological Approaches

Tricyclic Antidepressants

Several studies have reported benefit for clomipramine and imipramine in the treatment of panic disorder (Andersch et al. 1991; Cross-National Collaborative Panic Study 1992; Fahy et al. 1992; Lecrubier et al. 1997; Mavissakalian and Perel 1989; Modigh et al. 1992). The norepinephrine reuptake inhibitor desipramine also was more effective than placebo (Lydiard et al. 1993).

TCAs are second-line treatments for panic disorder at best. They are certainly effective, but the

associated autonomic side effects, cardiovascular problems, weight gain, and potential lethality in overdose are all matters of concern. Dosing with TCAs may be critical. Mavissakalian and Perel (1995), for example, found that phobic symptoms responded best if the plasma level of imipramine and desmethylimipramine was in the range of 110–140 ng/mL, whereas control of panic attacks tended to occur at lower plasma levels. As with SSRIs, low starting dosages in the range of 10–25 mg/day are in order, with gradual titration thereafter in accordance with patient tolerance.

Monoamine Oxidase Inhibitors

Sheehan et al. (1980) found that phenelzine, along with imipramine, was more effective than placebo in the treatment of panic disorder with agoraphobia, which they referred to as "endogenous anxiety." Lydiard and Ballenger (1987) expressed the opinion that MAOIs may be superior to TCAs. Although these debates were fruitful in the 1980s, MAOIs have been swept aside by the remorseless tide of history, as have TCAs to some degree. These drugs now have been relegated to a lower echelon. Although for some patients MAOIs may still be the best treatment, their overall role in managing anxiety disorders is now fairly small. The role of the safer reversible inhibitor of monoamine oxidase A (RIMA) in panic disorder is unclear. Brofaromine and moclobemide have shown comparable efficacy and tolerability to clomipramine (Bakish et al. 1993; Kruger and Dahl 1999) and moclobemide also to fluoxetine for up to 1 year (Tiller et al. 1999); however, the significance of these findings is questionable in the absence of a placebo control. When compared with CBT and placebo, the effect of moclobemide was no different from placebo and failed to enhance the effect of CBT (Loerch et al. 1999).

Other Drugs

The extended-release (XR) formulation of venlafaxine, a serotonin–norepinephrine reuptake inhibitor (SNRI), has demonstrated greater efficacy than placebo in patients with panic disorder (Bradwejn et al. 2005) and has received FDA approval for the treatment of panic disorder. Following 10 weeks of treatment, patients receiving venlafaxine XR (mean dosage = 163 mg/day) experienced fewer panic attacks, greater freedom from limited symptom attacks (but not full symptom attacks), improvement in anticipatory anxiety and avoidance, and higher rates of response and remission compared with placebo. The drug was well tolerated, with an adverse-effect profile comparable with that of the drug in depression and other anxiety disorders.

Mirtazapine, a noradrenergic and specific serotonergic antidepressant, has also demonstrated anxiolytic activity. Possible benefit in panic disorder has been reported for the drug (Boshuisen et al. 2001; Ribeiro et al. 2001; Sarchiapone et al. 2003); however, double-blind, placebo-controlled trials have yet to be conducted. It is noteworthy that mirtazapine has been associated with the induction of panic attacks in depressed patients undergoing dose escalation and discontinuation (Berigan 2003; Klesmer et al. 2000).

Reboxetine, a selective reuptake inhibitor of norepinephrine, has been found to produce greater benefit than placebo in patients with panic disorder (Versiani et al. 2002). At dosages of 6–8 mg/day, the drug produced greater improvement in the number of panic attacks and phobic symptoms, as well as reduction in score on the Hamilton Rating Scale for Depression (Ham-D; Hamilton 1960), the Hopkins Symptom Checklist–90, and the Sheehan Disability Scale. It also produced significantly higher levels of dry mouth than placebo but in general was well tolerated. In a more recent randomized, single-blind study comparing reboxetine with paroxetine, paroxetine was more effective on panic attacks, but no differences were noted between the treatments on anticipatory anxiety and avoidance (Bertani et al. 2004). These findings suggest perhaps different roles of norepinephrine and serotonin in the treatment of panic disorder. In those countries where reboxetine has been approved for depression and is therefore available, it might be a useful backup drug for use in SSRI and benzodiazepine nonresponders. Given its antidepressant properties, it might be advantageous over

benzodiazepines. However, the selective noradrenergic reuptake inhibitor maprotiline appears to be ineffective in panic disorder (Den Boer and Westenberg 1988), while the data for bupropion are inconclusive (Sheehan et al. 1983; Simon et al. 2003).

Trazodone was less effective than imipramine and alprazolam in the treatment of panic disorder (Charney et al. 1986). Buspirone, a 5-HT_{1A} partial agonist, was ineffective in panic disorder (Sheehan et al. 1990). The anticonvulsant gabapentin was also generally ineffective in panic disorder, though post hoc analyses suggest an anxiolytic effect in more severely ill patients (Pande et al. 2000). Possible benefit has been reported for other anticonvulsant drugs, including levetiracetam, tiagabine, and valproic acid (Keck et al. 1993; Papp 2006; Zwanzger et al. 2001), but double-blind trials have not been undertaken. Preliminary data suggest improvement in refractory panic disorder when atypical antipsychotics are prescribed to augment an SSRI (risperidone: Simon et al. 2006; olanzapine: Sepede et al. 2006) or at higher doses as monotherapy (olanzapine: Hollifield et al. 2005); however, double-blind, placebo-controlled trials are needed. Metabotropic glutamate type 2 receptor agonists have shown promise in preclinical models of anxiety but have yet to demonstrate clinical efficacy in panic disorder (Bergink and Westenberg 2005). Similarly, the effect of a cholecystokinin-B receptor antagonist was no different from placebo in patients with panic disorder (Pande et al. 1999a).

Combination Pharmacotherapy

The activating side effects of SSRIs can be quite troublesome for anxiety patients, particularly when beginning pharmacotherapy in patients with panic disorder. Coadministration of a long-acting benzodiazepine for the first several weeks of treatment may help improve SSRI tolerability and provide more rapid stabilization of panic symptoms than SSRI treatment alone (Goddard et al. 2001; Pollack et al. 2003).

Long-Term Management

Maintenance treatment is recommended for at least 12–24 months, if not longer. The long-term treatment of panic disorder has been reviewed elsewhere (Davidson 1998). In a controlled trial of paroxetine, clomipramine, and placebo, 84% of the paroxetine-treated patients eventually became panic free over the 9-month period (Lecrubier and Judge 1997). In a 4-year naturalistic follow-up study of 367 patients with panic disorder, greater improvements in panic attacks, phobic avoidance, and daily functioning were observed in those who received continuation treatment for 4 years, compared with 1 year (Katschnig et al. 1995), suggesting that recovery continues over several years.

Long-term randomized, controlled trials have reported efficacy for citalopram (Lepola et al. 1998), clomipramine (Fahy et al. 1992), fluoxetine (Michelson et al. 1999), paroxetine (Lecrubier and Judge 1997; Lydiard et al. 1998), and sertraline (Rapaport et al. 2001). In a relapse prevention trial following 3 months of successful open-label treatment with the drug, Ferguson et al. (2007) showed that over the course of 7 months, relapse on placebo was 50%, whereas relapse among those remaining on venlafaxine XR was 22%.

From an early long-term study of imipramine (Mavissakalian and Perel 1992), it appeared that relapse may diminish with the passage of time, provided effective psychopharmacological cover has been provided, but a later trial by the same group failed to confirm this (Mavissakalian and Perel 2002).

Discontinuation

Even though there is some similarity between symptoms of relapse and symptoms of drug withdrawal, the existence of discontinuation symptoms from stopping medication is unarguable. If poorly managed, discontinuation can be fraught with problems. Some strategies are likely to make withdrawal of medication more tolerable. The first strategy is a slow taper. Indeed, for some benzodiazepines, it may be necessary to taper the drug over many weeks or even months. Second, timing of the taper may be important. This is best accomplished when other variables in a patient's life

are as stable as possible. Switching to a longer-acting benzodiazepine, such as clonazepam, also may be helpful. Some authors (Pages and Ries 1998) have advocated consideration of anticonvulsants, such as carbamazepine and valproate. Otto et al. (1993) also found behavior therapy to be helpful in this regard.

Various elaborations of CBT, including self-help books, and telephone- and Internet-delivered therapy, have demonstrated efficacy on a consistent basis for panic disorder, with the common elements being education, cognitive strategies, and exposure to feared sensations and situations (Clum and Surls 1993; Royal Australian and New Zealand College of Psychiatrists Clinical Practice Guidelines Team for Panic Disorder and Agoraphobia 2003). CBT is a first-line choice, and even when pharmacotherapy is given as main treatment, principles of CBT should be incorporated into the management plan. As noted, it can be of benefit during the process of drug discontinuation, and perhaps in lessening the chance of relapse afterwards.

SOCIAL PHOBIA

Social phobia, also referred to as social anxiety disorder, can be grouped into generalized and nongeneralized types. Generalized social phobia is more commonly seen in clinical settings, is usually more disabling, and is associated with greater levels of comorbidity and genetic loading than nongeneralized social phobia. Most of our knowledge about pharmacotherapy for social phobia derives from generalized social phobia, and the literature suggests that different medication approaches may be called for in treating the two subtypes.

Comprehensive treatment of social phobia requires that the symptoms of fear, avoidance, and physiological distress are brought under control, comorbidity is treated, disability and impairment are improved, and quality of life is enhanced. Furthermore, evidence from maintenance and relapse prevention studies has confirmed the value of long-term therapy in treatment responders.

Instruments commonly used to measure treatment change in social phobia include the clinician- and self-rated Liebowitz Social Anxiety Scale (LSAS; Liebowitz 1987), which assesses 24 performance or interpersonal situations for fear and avoidance. A score of 30 or less is considered to equate with remission. The Social Phobia Inventory (SPIN) is a useful 17-item self-rating instrument that assesses fear, avoidance, and physiological distress (Connor et al. 2000) and, like the LSAS, is able to detect treatment differences on all its subscales.

Pharmacotherapy

Most clinicians consider SSRI drugs as the first choice for generalized social phobia, with either β -blockers or benzodiazepines being the first choice for nongeneralized social phobia. Second-line drugs for generalized social phobia comprise the benzodiazepines, perhaps venlafaxine (an SNRI), and maybe other antidepressants, including nefazodone and mirtazapine. MAOIs also have a role. Bupropion and TCAs have been generally disappointing.

Serotonergic Drugs

Fluvoxamine has been widely studied and has the longest track record of success in the treatment of social phobia. In 1994, van Vliet et al. showed superiority for fluvoxamine over placebo, with response rates of 46% and 7%, respectively. M. B. Stein et al. (1999) later confirmed the efficacy of fluvoxamine relative to placebo on all symptom domains of social phobia (i.e., fear, avoidance, and physiological arousal). Studies have also looked at the controlled-released (CR) form of fluvoxamine and found it to be superior to placebo (Davidson et al. 2004c; Westenberg et al. 2004). In the study by Davidson et al. (2004c), baseline symptom severity was higher than in most other clinical trials, yet drug therapy was still effective. In addition to these studies conducted in the United States or Europe, a more recent study in Japan also found fluvoxamine to be effective compared to placebo in reducing symptoms and associated psychosocial disability among Japanese patients with generalized social

anxiety disorder (Asakura et al. 2007).

Sertraline also has been studied (Blomhoff et al. 2001; Katzelnick et al. 1995; Liebowitz et al. 2003; Van Ameringen et al. 2001; Walker et al. 2000). In the study by Van Ameringen et al. (2001), 53% responded to sertraline as compared with 29% to placebo. As with the fluvoxamine study of M. B. Stein et al. (1999), the Brief Social Phobia Scale was a primary outcome measure, and in both instances, the drug was shown to produce benefit on all three symptom domains. In a primary care setting, Haug et al. (2000) showed that cognitive therapy and sertraline could be effectively delivered, although the combination did not really show any superiority over treatment with drug alone.

Effectiveness for paroxetine was shown relative to placebo in both short-term efficacy and relapse prevention. In the short-term studies by M. B. Stein et al. (1998), Allgulander (1999), and Baldwin et al. (1999), rates of response to paroxetine were 55%, 70%, and 66%, respectively, as compared with placebo response rates of 24%, 8%, and 32%. These differences are substantial and suggest a marked effect for paroxetine in social phobia. All subjects in the paroxetine trials fulfilled criteria for generalized social phobia and showed benefit on the primary measure, the LSAS. Between 2 and 4 weeks was required for paroxetine to show significant superiority.

Fluoxetine, while superior to placebo on primary outcomes in one study (Davidson et al. 2004c), failed to separate from placebo in another (Kobak et al. 2002). In the latter study, placebo seemed to yield a greater response (30%) than most other studies of SSRIs in social phobia. Another study comparing cognitive therapy, fluoxetine plus self-exposure, and placebo plus self-exposure in social phobia found cognitive therapy to be superior to fluoxetine plus self-exposure and placebo plus self-exposure on measures of social phobia, with no difference between the latter two groups (D. M. Clark et al. 2003). Interestingly, another serotonergic agent, nefazodone, also failed to separate from placebo on most outcome measures in a recent report of Canadian outpatients with social phobia (Van Ameringen et al. 2007).

Placebo-controlled data with citalopram have not been presented for social phobia. However, trials with escitalopram have shown superiority over placebo in short-term, long-term, and relapse prevention studies of generalized social phobia (Kasper et al. 2005; Lader et al. 2004; Montgomery et al. 2005). Venlafaxine XR has also shown superiority over placebo in two double-blind trials of generalized social phobia (Allgulander et al. 2004; Liebowitz et al. 2005). A double-blind, placebo-controlled trial of mirtazapine in women showed statistically significant superiority for drug over placebo (Muehlbacher et al. 2005).

Paroxetine, sertraline, and venlafaxine XR are currently the only FDA-approved drugs for the treatment of social phobia, although the controlled-release form of fluvoxamine is likely to be approved for social anxiety disorder in the near future.

Benzodiazepines

Three major placebo-controlled trials have shown efficacy for benzodiazepines in social phobia. First, Gelernter et al. (1991) showed a very modest effect for alprazolam over placebo and a generally inferior picture for alprazolam relative to phenelzine. The response rate with alprazolam, at a mean daily dose of 4.2 mg, was 38%, a rate significantly better than the 20% response rate to placebo. Davidson et al. (1993) conducted a moderately large trial in 75 patients taking clonazepam or placebo and found a substantial 70% response rate to clonazepam compared with a 20% response rate to placebo. Clonazepam worked rapidly and effectively and had a broad-spectrum effect in the disorder. Bromazepam also has been found to work more effectively than placebo (Versiani et al. 1997). A magnetic resonance spectroscopy study of clonazepam in social phobia has shown that even when clonazepam is effective, there are no changes in the extent of *N*-acetylaspartate, choline, and *myo*-inositol, suggesting that these particular changes within the central nervous system are not state

dependent.

Some benzodiazepines (clonazepam and bromazepam) provide a marked response yet do not find favor as first-line drugs because of their more limited spectrum of action, as well as potential withdrawal difficulties. However, they work rapidly, are well tolerated, and may be particularly useful for individuals with periodic performance-related social anxiety.

Anticonvulsants

Gabapentin and pregabalin produce significant effects in social phobia. Pande et al. (1999b) found a superior effect for gabapentin over placebo, with response rates of 39% and 17%, respectively. Baseline symptom scores were comparatively high and overall response rates relatively low, suggesting a degree of treatment resistance in the population. A flexible dosage of gabapentin was used, ranging from 900 to 3,600 mg, with 2,100 mg/day being the most commonly chosen final dosage. The newer anticonvulsant drug pregabalin has shown benefit in generalized social phobia. Although 150 mg/day of pregabalin was no different from placebo, 600 mg/day produced greater effects than placebo, with response rates of 43% and 22%, respectively. At 600 mg/day, pregabalin produces a relatively high rate of side effects, and it is probably necessary to explore lower dosages for social phobia. Further work with anticonvulsants is called for because they are generally well tolerated, safe, and less likely to produce difficulties during discontinuation than many SSRIs and benzodiazepines.

Reversible Inhibitors of Monoamine Oxidase

Moclobemide initially appeared to be a safer and very promising alternative to older MAOIs. A study by Versiani et al. (1992) showed that moclobemide worked almost as effectively as phenelzine and significantly better than placebo but that it was slower to take effect compared with phenelzine. Response rates to moclobemide and placebo in the study were 65% and 15%, respectively, with a fairly high dosage of moclobemide being attained (581 mg/day). However, these exciting early findings have not been borne out by subsequent studies. For instance, Noyes et al. (1997) reported no significant advantage for moclobemide at several dosages as compared with placebo. Schneier et al. (1998) showed a poor effect for the drug in a single-center trial, and the International Multicenter Clinical Trial Group on Moclobemide in Social Phobia (1997) found a modestly greater response rate (47%) for moclobemide at 600 mg/day than for placebo (34%). Based on the two positive trials, moclobemide has received a license in some countries but is not available in the United States. Another RIMA, brofaromine, has shown promise in three trials, with response rates of 78%, 50%, and 73%, respectively, compared with placebo response rates of 23%, 19%, and 0% (Fahlen et al. 1995; Lott et al. 1997; van Vliet et al. 1992).

Irreversible Inhibitors of Monoamine Oxidase

Phenelzine has been studied in four double-blind, placebo-controlled trials and showed positive benefit in all cases (Gelernter et al. 1991; Heimberg et al. 1998; Liebowitz et al. 1992; Versiani et al. 1992). Response rates to phenelzine were 69%, 85%, 64%, and 65%, respectively, as compared with 20%, 15%, 23%, and 33%, respectively, to placebo. Even though phenelzine is so consistently effective, perhaps as a result of its combined noradrenergic, dopaminergic, and serotonergic effects, its poor tolerance, as well as greater risks, makes it an unsuitable choice for most patients. However, it should not be completely ignored and may make a major difference in the lives of some patients whose symptoms do not respond to other drugs.

Other Drugs

Olanzapine yielded greater improvement than placebo in a preliminary double-blind, placebo-controlled monotherapy trial of social anxiety disorder (Barnett et al. 2002), suggesting atypical antipsychotics may deserve further investigation in this area of research. Ondansetron, while

producing a statistically significant effect relative to placebo, seems to be of very limited benefit (Bell and DeVeaugh-Geiss 1994; Davidson et al. 1997b), but it might be a useful backup or adjunct in some cases. Its cost is a major problem. Buspirone was ineffective in a double-blind trial, producing only a 7% response rate (van Vliet et al. 1997).

Despite their intuitive appeal, β-blockers have shown poor effect in treating generalized social phobia. For example, atenolol failed to separate from placebo in two trials (Liebowitz et al. 1992; Turner et al. 1994). β-Blockers do show some value in performance social anxiety, perhaps by virtue of their ability to reduce peripheral autonomic arousal and block negative feedback. Nefazodone, bupropion, and selegiline have not shown impressive results in open-label reports (Emmanuel et al. 1991; Simpson et al. 1998; Van Ameringen et al. 1999).

A novel therapeutic approach is suggested by the findings of Hofmann et al. (2006), who administered a single dose of D-cycloserine or placebo to patients with social anxiety disorder treated with CBT. The drug was given prior to each CBT session and enhanced the benefit of CBT to a greater extent than did placebo. The postulated mechanism of action relates to drug-facilitated extinction of learned fear via glutamatergic pathways.

Treatment in Children and Adolescents

One interesting placebo-controlled trial of fluvoxamine in children ages 6–17 years showed that it was superior to placebo in social phobia, GAD, or the combination: 76% of the fluvoxamine group responded, as compared with 19% of the placebo group (Research Unit on Pediatric Psychopharmacology Anxiety Study Group 2001). Double-blind trials of paroxetine immediate-release (IR) (Wagner et al. 2004) and venlafaxine XR (March et al. 2007) have produced positive results in children and adolescents with generalized social anxiety disorder. Response rates for paroxetine and placebo were 78% and 38%, respectively; in the venlafaxine study, they were 56% and 37%. An open-label trial by Compton et al. (2001) suggested some value for sertraline in children and adolescents with social phobia, but we are unaware of any published placebo-controlled trials.

Duration of Treatment

Because social phobia is a chronic illness, treatment is generally recommended for years. Sutherland et al. (1996) reported that at 2-year follow-up, subjects who had received an active drug rather than placebo in a double-blind trial were doing better. Relatively few relapse prevention studies have been done. In a 12-month trial with clonazepam, Connor et al. (1998) showed a 20% relapse rate in those switched to placebo compared with 0% in those who continued taking clonazepam. On other measures, there was an upward drift in fear and phobia scores in subjects who were withdrawn from clonazepam. However, in the study with its very slow taper, it was encouraging that withdrawal symptoms were rare and not problematic. M. B. Stein et al. (1996) reported that 62% of the subjects relapsed when switched double-blind from paroxetine to placebo after 12 weeks, compared with only 12% who relapsed during maintenance treatment with paroxetine.

Other Issues

CBT is efficacious in social anxiety disorder, being comparable to pharmacotherapy (Davidson et al. 2004b; Fedoroff and Taylor 2001), but little is known as to whether adding CBT to medication lowers the relapse rate, and so far the limited evidence does not suggest any potentiating effects when the treatments are combined (Davidson et al. 2004b). It does appear as if exposure consistently produces gain, but adding cognitive elements does not confer further benefit (Haug et al. 2003; Hofmann 2004). In a comparative study of drug and psychotherapy, Heimberg et al. (1998) showed that phenelzine and CBT were approximately similar, although phenelzine had an edge in more severely symptomatic patients. On the other hand, when subjects who had discontinued treatment were followed up, rates of relapse tended to be lower in those who had received CBT than in those who had

taken phenelzine. Turner et al. (1994) found that atenolol was not as good as social skills training, and D. B. Clark and Agras (1991) showed a relatively poor response with buspirone over exposure therapy in performance social phobia.

Despite the obvious benefits of drug therapy in social phobia, medication often falls short of producing remission, and a pressing need remains to find better drugs, better combinations, and the ways in which drug therapy and psychosocial treatments might be most productively used, whether in sequence, simultaneously, or according to some other formula. Nevertheless, compared with the situation 15 years ago, prospects for recovery from social phobia are perhaps better than they have ever been.

SPECIFIC PHOBIA

Specific phobia is among the most common psychiatric disorders, with a lifetime prevalence of 8%–12.5% (Alonso et al. 2004; Kessler et al. 2005b) and 12-month prevalence of 3.5%–9% (Alonso et al. 2004; Kessler et al. 2005a). While the disorder is characterized by an early age of onset (median age at onset is 7 years) (Kessler et al. 2005b), most of those with the disorder are unimpaired by their symptoms; hence, few individuals actually seek treatment for their specific phobia (Magee et al. 1996; Stinson et al. 2007; Zimmerman and Mattia 2000). However, for a minority of individuals, specific phobia causes significant disability and requires treatment. The generally accepted treatment of choice is exposure therapy, which is uniformly and rapidly effective, with techniques including virtual reality or in vivo exposure, and muscle tension exercises (for blood–injury phobia) (Swinson et al. 2006). Few studies have evaluated the efficacy of pharmacological approaches, and no drug has yet been approved by the FDA for treating specific phobia. No standard ratings exist for this disorder, although the Marks-Matthews FQ is quite suitable for blood–injury phobia and some other fears. A modification of this scale, the Marks-Sheehan Main Phobia Severity Scale (MSMPSS; Sheehan 1986) can be recommended.

Serotonergic drugs have shown efficacy in treating symptoms of fear and avoidance in a variety of anxiety disorders and thus would seem logical choices in treating specific phobias. It is therefore not surprising that studies of pharmacological treatments for specific phobia have focused on serotonergic agents. In a double-blind, controlled trial, 11 subjects were treated for 4 weeks with either paroxetine (up to 20 mg/day) or placebo (Benjamin et al. 2000). As measured by the Marks-Matthews FQ and the Ham-A, 60% of the subjects (3 of 5), compared with 17% taking placebo (1 of 6), responded to treatment with paroxetine. A more recent randomized, double-blind pilot trial compared the effects of escitalopram versus placebo over 12 weeks in 12 adults with specific phobia (Alamy et al. 2008). While no difference was observed on the primary outcome, response based on a Clinical Global Impression Scale (CGI) Improvement score of 1 or 2 was noted in 60% of subjects who received escitalopram, compared with 29% on placebo (effect size = 1.13). The findings from these two small trials suggest promise for the SSRIs in specific phobia; however, larger controlled trials are needed. In contrast, in a controlled trial of the serotonergic and noradrenergic drug imipramine in 218 phobic subjects (agoraphobic, mixed phobic, or simple phobic) receiving 26 weeks of behavior therapy, no difference was observed between imipramine and placebo (Zitrin et al. 1983). Intermittent use of benzodiazepines also may be helpful in the acute treatment of the somatic anxiety that accompanies specific phobia, although this usage has not been an area of active investigation.

In a long-term controlled study of clonazepam in social phobia, Davidson et al. (1994) observed that clonazepam was superior in reducing symptoms of anxiety related to blood–injury phobia as measured by changes in the blood–injury phobia subscale of the Marks-Matthews FQ. Some caution should be used with these drugs, however, because there is risk of physiological dependence.

Using a novel approach, Ressler et al. (2004) investigated the effect of a cognitive enhancer, D-cycloserine, as an adjunct to psychotherapy, hypothesizing that the drug would accelerate the

associative learning processes that contribute to ameliorating psychopathology. D-Cycloserine is a *N*-methyl-D-aspartate (NMDA) receptor partial agonist that has demonstrated improvement in extinction in rodents. Subjects with acrophobia (*n* = 28) were randomized to receive a single dose of D-cycloserine or placebo prior to each of two virtual reality exposure therapy sessions. The combination of D-cycloserine and exposure therapy was associated with greater improvement in the virtual-reality setting, as well as on a variety of anxiety domains. These changes were noted early in treatment and were maintained at 3-month follow-up.

Specific phobia tends to be a chronic condition. Although psychotherapeutic approaches can be beneficial in the short term, evidence suggests that the initial gains noted with treatment may not be sustained over the long term (Lipsitz et al. 1999). Pharmacological augmentation may help to extend the benefits of exposure therapy over time. It also has been hypothesized that specific phobia may represent a phenomenological marker for a vulnerability to developing other anxiety disorders that are characterized by more general avoidance (Goisman et al. 1998). As such, perhaps early recognition and treatment in individuals at risk could reduce the occurrence of more severe anxiety disorders in this population. Further study of these hypotheses is needed.

GENERALIZED ANXIETY DISORDER

GAD is a common anxiety disorder, with a lifetime prevalence of 5%–6% (Wittchen and Hoyer 2001) and is the most prevalent anxiety disorder in primary care, with rates that exceed 8% (Goldberg and Lecrubier 1995). GAD tends to be a chronic and disabling condition with lifetime rates of comorbidity as high as 90% (Wittchen et al. 1994), particularly depression (prevalence rate greater than 60%) (Wittchen et al. 1994), which can increase the severity and burden of the disorder.

GAD is characterized by persistent and excessive worry that is difficult to control and is accompanied by symptoms of anxiety, tension, and autonomic arousal. Effective treatments include anxiolytic drugs, such as benzodiazepines and azapirones. These drugs can be helpful for symptoms of anxiety, but they are not generally considered satisfactory in the treatment of depression. In addition, the side-effect profile of benzodiazepines and potential for physiological dependence limit their use in many patients and have resulted in growing interest in the search for alternative treatments. In recent years, growing evidence supports the role for antidepressants in treating GAD, especially in patients with comorbid depression.

The goals of pharmacotherapy for GAD include treatment of the symptoms of worry, anxiety, tension, somatic distress, and autonomic arousal. Ideally, treatments will have a rapid onset of action in reducing these core symptoms; will be effective in treating the associated disability, psychosocial impairment, and comorbidity; and will be safe for longer-term use in chronic GAD.

Assessment of response in almost all pharmacotherapy trials of GAD has involved use of the clinician-administered Ham-A (Hamilton 1959), which measures psychic (i.e., psychological) and somatic symptoms of anxiety and broadly maps onto the clinical features of GAD. Remission is usually defined as a Ham-A score of 7 or less. The Hospital Anxiety and Depression Scale (HADS; Zigmond and Snaith 1983) is also widely used and is capable of detecting differences in treatment efficacy. An advantage of the HADS lies in the fact that its items are independent from the confounding influence of psychotropic drug side effects. It also has widely established population norms.

Anxiolytics

Benzodiazepines

Benzodiazepines have been widely used to treat acute and chronic anxiety since their introduction in the 1960s. Their activity is mediated through potentiation of the inhibitory neurotransmitter γ-aminobutyric acid (GABA) at the $GABA_A$ receptor. The efficacy and relative safety of benzodiazepines

in short-term use, over several weeks or months, are well established (Rickels et al. 1983; Shader and Greenblatt 1993). However, the use of these drugs over longer periods is more controversial, and long-term use can be associated with the development of tolerance, physiological dependence, and withdrawal (if abruptly discontinued), as well as troublesome side effects, including ataxia, sedation, motor dysfunction, and cognitive impairment. Furthermore, these drugs should be avoided in patients with a history of substance use disorders, and long-term use may infrequently lead to the development of major depression (Lydiard et al. 1987).

Benzodiazepines have been shown to be effective in GAD, as reported by Rickels et al. (1993) in an 8-week study of diazepam in patients with DSM-III (American Psychiatric Association 1980)–diagnosed GAD. The appeal of these drugs lies in their rapid onset of action, ease of use, tolerability, and relative safety. However, few controlled data support their use over the long term in GAD. Findings from several 6- to 8-month trials of maintenance treatment for chronic anxiety have indicated continued efficacy of benzodiazepines over time (Rickels et al. 1983, 1988a, 1988b; Schweizer et al. 1993). Because GAD tends to be a chronic disorder, many patients may need to continue pharmacotherapy with benzodiazepines or other drugs for many years.

Estimates suggest that approximately 70% of patients with GAD will respond to an adequate trial of a benzodiazepine (Greenblatt et al. 1983). An adequate treatment trial corresponds to the equivalent of a 3- to 4-week treatment course of up to 40 mg/day of diazepam or 4 mg/day of alprazolam (Schweizer and Rickels 1996). If a decision is made to discontinue treatment, the drug should be tapered slowly to minimize the effects of withdrawal, the development of rebound anxiety, and the potential for relapse. Some evidence suggests that benzodiazepines may be more effective in treating particular GAD symptoms, such as autonomic arousal and somatic symptoms, but less effective for the psychic symptoms of worry and irritability (Rickels et al. 1982; Rosenbaum et al. 1984).

As our understanding of the phenomenology of GAD has grown and as the diagnostic criteria have evolved from DSM-III to DSM-IV (American Psychiatric Association 1994), there has been a greater emphasis on the psychic component of the disorder, with de-emphasis of the autonomic and somatic components. Given these changes, along with the high rates of comorbid depression in GAD and the anxiolytic activity of many of the newer classes of antidepressants, the utility of benzodiazepines as a primary treatment for GAD is uncertain. However, even though somatic symptoms are no longer featured as diagnostic criteria, they are frequently seen as presenting clinical symptoms in practice. A degree of uncertainty still hangs over the most appropriate way to classify GAD. Even as DSM-IV was being crafted, debate centered around the extent to which GAD could be separated from mood disorders, such as dysthymia and major depression (Moras et al. 1996). This question has never been well resolved, and it is possible that with so much in common between GAD and depressive disorders, its classification primarily as an anxiety disorder may change in DSM-V.

Azapirones

The azapirones are structurally distinct from the benzodiazepines and are believed to exert their anxiolytic effect through partial agonism of 5-HT_{1A} receptors. Several trials have indicated that buspirone is superior to placebo and comparable to benzodiazepines in treating GAD, with fewer side effects and without concerns for abuse, dependence, and withdrawal (Cohn et al. 1986; Enkelmann 1991; Petracca et al. 1990; Rickels et al. 1988b; Strand et al. 1990), although other studies have reported conflicting results (Fontaine et al. 1987; Olajide and Lader 1987; Ross and Matas 1987). Buspirone appears more effective in treating the psychic component of anxiety (Rickels et al. 1982) and possibly anxiety with mixed depressive symptoms (Rickels et al. 1991) than the somatic and autonomic symptoms of anxiety (Schweizer and Rickels 1988; Sheehan et al. 1990). An adequate trial of buspirone in GAD would be 3–4 weeks of treatment at a dosage of up to 60 mg/day, in divided doses. Treatment-limiting effects of the drug include greater potential for side effects at higher dosages, slower onset of action, more variable antidepressant effect, and possibly reduced

effectiveness in patients with a prior favorable response to benzodiazepines (Schweizer et al. 1986).

Tricyclic Antidepressants

Retrospective studies of subjects with "anxiety neurosis" suggested that TCAs may be effective in treating anxiety states similar to GAD (Cohn et al. 1986; Johnstone et al. 1980). Data in support of these findings come from controlled studies of imipramine and trazodone in GAD (Hoehn-Saric et al. 1988; Rickels et al. 1993). In a 6-week trial comparing imipramine and alprazolam, similar improvement was observed with both treatments by week 2; however, imipramine appeared to be more effective in treating the psychic anxiety associated with GAD, whereas alprazolam was more effective in attenuating somatic symptoms (Hoehn-Saric et al. 1988). In an 8-week double-blind, placebo-controlled trial of imipramine, trazodone, and diazepam (Rickels et al. 1993), early onset of effect was noted with diazepam by week 2, with effect primarily on somatic symptoms. Over the next 6 weeks, however, symptoms of psychic anxiety were more responsive to treatment with the antidepressants. Overall, imipramine was more efficacious than diazepam, whereas the effect of trazodone was comparable to that of diazepam, and all treatments were superior to placebo. In a controlled trial comparing imipramine, paroxetine, and 2'-chlordesmethyldiazepam, early onset of action was again noted with the benzodiazepine by week 2, but overall greater improvement was noted with the antidepressants by week 4, with particular benefit noted in psychic symptoms (Rocca et al. 1997).

Potential advantages of the TCAs over the benzodiazepines include their ability to treat symptoms of both anxiety and depression, the absence of potential for abuse and physiological dependence, and their effectiveness in the management of discontinuation of long-term benzodiazepine therapy (Rickels et al. 2000a). TCAs, however, can be accompanied by a variety of troublesome side effects related to pharmacological blockade of histamine$_1$ (H_1), α_1-adrenergic, and muscarinic receptors, and these effects can limit their use. Frequently reported adverse effects include weight gain, orthostatic hypotension, edema, urinary retention, blurred vision, dry mouth, and constipation. Sedation is also commonly noted; for some patients this is an adverse event, whereas for others it is of therapeutic benefit. The utility of the TCAs is also limited by their cardiotoxic potential and lethality in overdose.

Selective Serotonin Reuptake Inhibitors and Serotonin–Norepinephrine Reuptake Inhibitors

A number of SSRIs are effective in GAD. Paroxetine IR at 20–50 mg per day has been shown to be as effective as imipramine and more effective than 2'-chlordesmethyldiazepam, with the antidepressants again demonstrating greatest effect on symptoms of psychic anxiety (Rocca et al. 1997). Compared with placebo, a similar dosage range of paroxetine IR was associated with significant reduction in anxiety after 8 weeks of treatment (Bellew et al. 2000; Pollack et al. 2001), with an improvement in psychic anxiety as measured by reduction in the anxious mood item of the Ham-A scale, observed as early as 1 week after initiating treatment (Pollack et al. 2001). Paroxetine IR also improves social functioning in patients with GAD (Bellew et al. 2000). Rickels et al. (2003) have reported superior benefit of paroxetine IR in GAD, relative to placebo.

Three 8-week placebo-controlled trials have found efficacy for escitalopram in a 10- to 20-mg dose range on a variety of measures, of both anxiety symptoms and disability or quality of life (Davidson et al. 2004a; Goodman et al. 2005). In a 6-month trial, Bielski et al. (2005) found equivalent benefit for paroxetine IR and escitalopram. In a larger placebo-controlled trial of three doses of escitalopram and 20 mg paroxetine IR, 10 mg escitalopram demonstrated superiority over 20 mg paroxetine, 10 and 20 mg escitalopram were superior to placebo, while 5 mg escitalopram and 20 mg paroxetine IR were superior on some secondary outcomes (Baldwin et al. 2006). A relapse prevention study found that sustained treatment with escitalopram 20 mg/day up to 74 weeks reduced the rate of relapse relative to placebo substitution (Allgulander et al. 2006). Relapse rates were for 19% for escitalopram versus

56% for placebo.

Two studies have shown benefit for sertraline over placebo in GAD (Allgulander et al. 2004; Brawman-Mintzer et al. 2006).

Several placebo-controlled trials have confirmed the short-term efficacy of venlafaxine XR in GAD over 8 weeks, with improvement noted in both the psychic and the somatic symptoms of the disorder. In one trial, 365 adult outpatients received treatment with venlafaxine XR (75 mg/day or 150 mg/day), buspirone (30 mg/day), or placebo (Davidson et al. 1999). The adjusted mean scores on the Ham-A anxious mood and tension items were significantly improved at both dosages of venlafaxine XR compared with placebo; however, the adjusted mean Ham-A total score failed to distinguish between the groups. Venlafaxine XR was superior to buspirone on the Anxiety subscale of the HADS. In a second trial, 541 outpatients were given either venlafaxine XR (37.5 mg/day, 75 mg/day, or 150 mg/day) or placebo (Allgulander et al. 2001). By the end of the study, the 75-mg and 150-mg doses of venlafaxine showed superior efficacy to placebo on all primary outcome measures, whereas the 37.5-mg dose was superior on only one measure (the Anxiety subscale of the HADS). Significant improvement was noted in symptoms of psychic anxiety by week 2 of treatment with venlafaxine, with reduction of somatic symptoms noted a bit later, following 4–8 weeks of treatment. A third trial evaluated fixed dosages of venlafaxine XR at 75 mg/day, 150 mg/day, and 225 mg/day (Rickels et al. 2000b). Venlafaxine XR was superior to placebo on all outcome measures, although the most robust effects were observed with 225 mg/day. In addition, venlafaxine XR significantly reduced psychic anxiety but was no different from placebo in treating somatic symptoms of anxiety.

Venlafaxine XR also has shown long-term efficacy in GAD. In two 6-month controlled trials of fixed (37.5 mg, 75 mg, 150 mg/day) (Allgulander et al. 2001) and flexible (75–225 mg/day) (Gelenberg et al. 2000) doses of venlafaxine XR, significant improvement in anxiety was observed as early as 1 week, and efficacy was sustained over the 28-week treatment period. In the fixed-dose study, the greatest effect was observed with the 150-mg/day dose. In addition, significant improvement in social functioning was noted at the two higher doses by week 8 and sustained over the 6 months of the trial.

Venlafaxine XR is also effective in treating GAD with comorbid depression (Silverstone and Salinas 2001). After 12 weeks of treatment with venlafaxine XR (75–225 mg/day), fluoxetine, or placebo, significant reduction was observed in both anxiety and depression, as measured by the Ham-A and the Ham-D, respectively, only in subjects receiving venlafaxine XR. The response was delayed somewhat in subjects with comorbid GAD and depression, as compared with those with depression alone, suggesting that those with comorbidity may benefit from a longer course of treatment.

The traditional treatment goal for GAD and many other psychiatric disorders has been attainment of response, defined as 50% improvement relative to baseline. There is a growing consensus in the field, however, that this goal is not sufficient for many patients and that the goal of treatment should instead be remission, defined as 70% or greater improvement from baseline and/or minimal or absent symptoms (i.e., Ham-A score ≤7). Pooled analysis of data from the two long-term studies noted above has determined that remission is attainable in GAD (Meoni and Hackett 2000). By 2 months, approximately 40% of those receiving venlafaxine responded to treatment (response defined as ≥50% reduction in Ham-A score from baseline), and 42% attained remission (defined as a Ham-A score ≤7). By 6 months, the proportion of those in remission increased to almost 60%, whereas responders declined to 20%, in contrast to a remission rate of less than 40% with placebo.

Venlafaxine XR has some advantages over the benzodiazepines—notably, antidepressant activity, lack of potential for abuse and dependence, and efficacy in treating symptoms of psychic anxiety. Nonetheless, venlafaxine can be associated with some adverse effects, even though the incidence of these effects diminishes markedly with long-term treatment. Adverse events may be noted with

long-term therapy, however, and include sexual dysfunction and blood pressure elevation in some patients. In addition, abrupt discontinuation of treatment can be associated with unpleasant side effects, most commonly dizziness, light-headedness, tinnitus, nausea, vomiting, and loss of appetite, and the discontinuation syndrome is worse if one abruptly stops from higher dosage levels (Allgulander et al. 2001).

Duloxetine, also an SNRI antidepressant, has shown superior efficacy to placebo in GAD (Allgulander et al. 2007; Rynn et al. 2008) in the range of 60–120 mg per day, as well as lessening the chance of relapse during maintenance therapy.

Noradrenergic and Specific Serotonergic Antidepressants (Mirtazapine, Bupropion)

The antidepressant mirtazapine also has demonstrated anxiolytic properties (Ribeiro et al. 2001). However, published reports of its effect in GAD are limited to a small open-label study in major depression and comorbid GAD (Goodnick et al. 1999). Although the results were encouraging, data from controlled trials are needed to adequately assess a possible role for mirtazapine in GAD.

One double-blind trial, published in abstract form, found that bupropion XL produced a higher remission rate than escitalopram, as well as better coping skills (Bystritsky et al. 2005). Notwithstanding these intriguing findings, the body of clinical evidence for now supports the use of serotonergic drugs, or dual serotonergic/noradrenergic reuptake inhibitors, before agents that are primarily noradrenergic in action. However, the Bystritsky et al. findings suggest the potential importance of noradrenergic mechanisms in GAD and its therapeutics.

Hydroxyzine

Hydroxyzine, a drug that blocks both H_1 and muscarinic receptors, has been studied in GAD. In one controlled study, hydroxyzine was superior to placebo following 1 week of treatment, and this difference was maintained over a 4-week trial (Ferreri and Hantouche 1998). In a larger controlled multicenter trial, hydroxyzine was compared with buspirone over 4 weeks (Lader and Scotto 1998). Changes in the Ham-A from baseline to day 28 indicated that hydroxyzine was superior to placebo, with no difference observed between buspirone and placebo. Of note, both hydroxyzine and buspirone were more efficacious than placebo on the secondary outcomes. Llorca et al. (2002) found that hydroxyzine 50 mg/day was superior to placebo and comparable to bromazepam in a 12-week trial.

Other Drugs

The $\alpha_2\delta$ calcium channel antagonist pregabalin was superior to placebo in four studies of GAD (Feltner et al. 2003; Pande et al. 2003; Pohl et al. 2005; Rickels et al. 2005). Efficacy was noted early in treatment, but the ability of this drug to successfully treat some of the comorbid disorders found with GAD is unknown. The GABA reuptake inhibitor tiagabine failed to separate from placebo on key measures in one multicenter trial (Pollack et al. 2005).

Evidence for antipsychotic monotherapy in GAD is limited. An open-label trial suggested benefit for ziprasidone (Snyderman et al. 2005). Flupenthixol is approved for the use of depression in some countries but is also widely used to treat GAD-like states. One controlled study showed that flupenthixol was superior to amitriptyline, clotiazepam, and placebo among subjects with refractory GAD (Wurthmann et al. 1995). Sulpiride is also used in similar situations (Bruscky et al. 1974; Chen et al. 1994). Use of antipsychotic drugs carries some concern about their tolerability and safety profile.

Riluzole, a presynaptic glutamate release inhibitor, has shown promise in a small open-label study at a daily dose of 100 mg (Mathew et al. 2005).

Complementary treatments, such as homeopathy and the herbal remedy kava kava, are ineffective in GAD (Bonne et al. 2003; Connor and Davidson 2002).

A meta-analysis of GAD studies by Hidalgo et al. (2007) showed that the effect sizes (in diminishing order from strongest to weakest) for each drug or drug group versus placebo were as follows: pregabalin, 0.50; hydroxyzine, 0.45; venlafaxine XR, 0.42; benzodiazepines, 0.38; SSRIs, 0.36; buspirone, 0.17; and homeopathy and herbal treatment, –0.31.

Drugs that have been approved in the United States for treating GAD or historical forerunners of the disorder include a large number of benzodiazepines, buspirone, paroxetine IR, escitalopram, venlafaxine XR, and duloxetine.

There is also convincing evidence in favor of efficacy for CBT in GAD, with sustained benefit over 2 years of follow-up. These findings have been well reviewed by Swinson et al. (2006). There are no clinically informative studies to compare, or combine, CBT and pharmacotherapy in GAD, but on pragmatic grounds, one may consider their combination in patients who have shown only a partial response to a thorough course of either CBT or medication alone.

POSTTRAUMATIC STRESS DISORDER

PTSD is a chronic and disabling disorder, with a lifetime prevalence of about 7% (Kessler et al. 2005a). The direct and indirect consequences of the disorder inflict an enormous burden on society, leading PTSD to be the primary cost driver in the annual $42 billion cost of anxiety disorders in the late 1990s (P. E. Greenberg et al. 1999).

Treatment of PTSD should target a range of presenting features. Clearly, effective therapy needs to reduce the core symptoms of the disorder. Treatment also should focus on improving resilience and coping with daily stress, improving quality of life, and reducing comorbidity and disability. For some, medication may serve to help seal over the distress and pain of the event and allow a return to normal daily activities. For others, medication may help them to engage in a treatment plan that involves uncovering the distress and allows for resolution of the traumatic experience.

Instruments that have been widely used in trials of pharmacotherapy comprise the DSM-IV criteria–linked Clinician-Administered PTSD Scale (CAPS; Weathers et al. 2001) and the more globally oriented Short PTSD Rating Instrument (SPRINT; Connor and Davidson 2001). Self-rating scales include the Davidson Trauma Scale (DTS; Davidson et al. 1997a), a 17-item, two-part assessment of the major DSM-IV symptoms of PTSD, and the SPRINT, which also has been validated as a self-rating. Most studies to date have evaluated monotherapy, but a growing number are examining augmentation approaches.

Antidepressants

The TCAs and MAOIs were among the first pharmacological agents studied in controlled trials of PTSD. More recently, findings from several controlled multicenter trials have shown efficacy for the SSRI and SNRI drugs. With the documented antidepressant and anxiolytic effects of these noradrenergic and serotonergic agents, and the high rates of comorbid depression in PTSD (Kessler et al. 1995), antidepressants would seem like a logical choice for treatment of PTSD.

Tricyclic Antidepressants

Positive evidence for the efficacy of TCAs has been found in two controlled trials involving male combat veterans with PTSD defined by DSM-III criteria. In one study, 46 World War II and Vietnam War veterans were given amitriptyline (50–300 mg/day) or placebo for 8 weeks. Greater improvement was noted with amitriptyline than with placebo; 50% of those receiving amitriptyline showed much or very much global improvement, compared with 17% of those receiving placebo (Davidson et al. 1990). A second study examined imipramine (50–300 mg/day) and placebo in 60 veterans of the Vietnam era. Greater reduction in symptoms was noted in subjects receiving imipramine, with a 25% reduction in Impact of Event Scale (IES; Horowitz et al. 1979) score from

baseline for imipramine compared with 5% for placebo. Global improvement also was superior with imipramine (65%) compared with placebo (28%) (Kosten et al. 1991). Together, these studies showed that TCAs are more effective than placebo in the short-term treatment of PTSD in male combat veterans.

Monoamine Oxidase Inhibitors

In a study of male combat veterans, Kosten et al. (1991) compared phenelzine (15–75 mg/day) with placebo and found a 45% decrease in IES score from baseline for phenelzine, compared with a 5% decrease for placebo, but no improvement was noted in depressive symptoms with either treatment. The RIMA brofaromine has been assessed in two controlled trials of PTSD: a U.S. sample composed predominantly of combat veterans (n = 114) (Baker et al. 1995) and a civilian European sample with few veterans (n = 68) (Katz et al. 1994). The U.S. study failed to show a difference between the treatments. Findings from the European study also were mixed, depending on the measure used to assess change. Finally, the RIMA moclobemide was assessed in 20 subjects with PTSD meeting DSM-III-R (American Psychiatric Association 1987) criteria (Neal et al. 1997). Following 12 weeks of treatment, 11 subjects no longer met the full PTSD criteria, providing a signal that the drug might be effective in PTSD.

Selective Serotonin Reuptake Inhibitors

Three controlled trials support the efficacy of fluoxetine in PTSD. In these studies, fluoxetine was administered at dosages of 20–80 mg/day for 5–12 weeks in samples including both civilians and combat veterans with PTSD meeting DSM-III-R (Connor et al. 1999; van der Kolk et al. 1994) or DSM-IV (Martenyi et al. 2002a) criteria. Significant differences were observed in favor of fluoxetine, as measured by changes in clinician-rated structured interviews from baseline to the end of treatment. In the study by Connor et al. (1999), fluoxetine also was associated with a significant improvement in resilience, as measured by a reduction in stress vulnerability, and in disability. Martenyi et al. (2002a) showed that at a mean dosage of 57 mg/day, fluoxetine was associated with significant reduction in PTSD symptoms from baseline as early as week 6 and at week 12, in a sample predominantly made up of male combat veterans.

Two studies of maintenance therapy with fluoxetine over a period of 1 year have shown reductions in the rate of relapse, as compared with placebo substitution (Davidson et al. 2005; Martenyi et al. 2002b).

Two studies have shown efficacy for sertraline in PTSD (Brady et al. 2000; Davidson et al. 2001). At a mean dosage of approximately 150 mg/day, sertraline was more effective than placebo in reducing overall PTSD symptoms and avoidance; symptoms of arousal improved with sertraline in one study (Brady et al. 2000; Davidson et al. 2001), but no differences were noted in intrusive symptoms. Based on a response definition of a greater than 30% reduction in CAPS (Blake et al. 1995) score from baseline and a CGI score of 1 or 2 (much or very much improvement), response rates for sertraline ranged from 53% to 60%, compared with 32%–38% for placebo. A pooled analysis of these data showed the broad-spectrum effect of the drug, particularly on psychological symptoms of the disorder, with an early modulation of anger at 1 week preceding improvement in other symptoms (Davidson et al. 2002). This finding is of particular interest, given that angry temperament can be associated with impulsivity and violence and a greater risk for cardiac events (Williams et al. 2001), as well as increased heart rate and blood pressure, in PTSD (Beckham et al. 2002). Other short-term studies of sertraline in PTSD have been negative (Brady et al. 2005; Davidson et al. 2006b; Friedman et al. 2007) or inconclusive (Zohar et al. 2002).

Continued treatment with sertraline over 9 months was associated with sustained improvement in more than 90% of the subjects (Londborg et al. 2001). In those with more severe PTSD who did not improve with acute treatment over 12 weeks, more than 50% were likely to respond with continued

treatment (Londborg et al. 2001). Over 15 months of treatment, improvement was sustained, with relapse rates of 5% with sertraline and 26% with placebo, thereby suggesting that the drug provides prophylactic protection against relapse (Davidson et al. 2001). Sertraline is also effective in improving quality of life and reducing functional impairment, with rapid improvement noted with acute treatment and more than 55% of patients functioning at levels within 10% of the general population. These gains are maintained with long-term treatment, and continued improvement can be noted, whereas treatment discontinuation is more likely to lead to deteriorating function, although not to levels observed prior to treatment (Rapaport et al. 2002).

The efficacy of paroxetine in PTSD has been shown in two 12-week controlled multicenter trials, including flexible-dose (*n* = 307; paroxetine 20–50 mg) (Tucker et al. 2001) and fixed-dose (*n* = 451; paroxetine 20 or 40 mg) (Marshall et al. 2001) regimens. Compared with placebo, paroxetine produced significant improvement in overall PTSD symptomatology, individual symptom clusters, and functional impairment. Response rates ranged from 54% to 62% for paroxetine compared with 37% to 40% for placebo.

Findings from two open-label studies of fluvoxamine, at dosages of 100–250 mg/day, have been reported, including those from an 8-week study in civilians (*n* = 15) and a 10-week study in combat veterans (*n* = 10) (Davidson et al. 1998; Marmar et al. 1996), in which the drug was effective in treating symptoms of PTSD. Treatment with fluvoxamine (mean = 194 mg/day) also has been associated with significant improvement in autonomic reactivity, with reductions in heart rate and blood pressure on exposure to trauma cues to levels that are indistinguishable from those of control subjects without PTSD (Tucker et al. 2000). These findings are encouraging, but larger controlled trials are needed to determine the efficacy of the drug in PTSD.

Two large multicenter studies have established efficacy for venlafaxine XR up to 300 mg per day, in one case for as long as 6 months. Rates of remission exceeded 50% in the longer-term trial, and resilience was significantly improved in one of the two studies (Davidson et al. 2006a, 2006b).

In summary, the SSRIs are efficacious in the treatment of PTSD, with two drugs, paroxetine IR and sertraline, approved for treatment of PTSD. SSRIs and SNRIs show a broad spectrum of activity, with significant reduction in some symptoms as early as 1–2 weeks after treatment initiation. SSRI and SNRI drugs not only improve symptoms with acute treatment but also result in sustained and continued improvement, and in some cases remission, with long-term treatment up to 15 months. These drugs are generally well tolerated, although some adverse effects (e.g., sexual dysfunction, sleep disturbances, and weight gain) may lead to treatment discontinuation.

Other Antidepressants

Results of one 8-week controlled trial of mirtazapine in 29 outpatients with PTSD have been reported. A clinician-rated global assessment found response rates to mirtazapine of 65% compared with response rates to placebo of 20%, with significant improvement on several measures of PTSD as well as general anxiety (Davidson et al. 2003).

Six open-label studies of nefazodone in civilians and combat veterans with PTSD have been reported (Hidalgo et al. 1999). Treatment with nefazodone (50–600 mg/day) over 6–12 weeks was associated with significant reduction in severity of overall PTSD, as well as in each of the symptom clusters. Of particular note was improvement in sleep, which is often disrupted in PTSD, and these problems are frequently exacerbated by treatment with SSRIs. Davis et al. (2004) have demonstrated superior efficacy for the drug, relative to placebo, in combat veterans.

Anxiolytics

Benzodiazepines are often prescribed to treat acute anxiety in the aftermath of a trauma. However, findings have been disappointing. An open-label study of alprazolam and clonazepam in 13

outpatients with PTSD found reduced hyperarousal symptoms but no change in intrusion or avoidance/numbing (Gelpin et al. 1996). In a crossover design, subjects received 5 weeks of treatment with either alprazolam or placebo followed by 5 weeks of the alternative therapy (Braun et al. 1990). Minimal improvement was observed in anxiety symptoms overall, with no improvement in the core symptoms of PTSD. Clonazepam 2 mg was not different from placebo in controlling nightmares in a 2-week single-blind crossover study, where the test drug was added to preexisting treatment (Cates et al. 2004). Thus, the evidence does not yet support the use of benzodiazepines in PTSD, even though they appear to be widely used (Mellman et al. 2003). Their position in managing PTSD thus remains unclear.

Anticonvulsants

In the 1980s, Lipper et al. (1986) proposed that the pathophysiology of PTSD may involve sensitization and kindling processes and, to this end, that anticonvulsants might be of therapeutic benefit. In testing this hypothesis, these investigators found that 7 of 10 (70%) Vietnam War veterans who received open-label carbamazepine (600–1,000 mg/day) for 5 weeks had "moderate" or "very much" improvement with treatment, particularly in symptoms of intrusion and hyperarousal. Three subsequent open-label studies have been performed, including two with sodium valproate in combat veterans (R. D. Clark et al. 1999; Fesler 1991) and a study of adjunctive topiramate in a civilian PTSD sample (Berlant and van Kammen 2002). The treatments showed somewhat different effects, with sodium valproate (250–2,000 mg/day) improving symptoms of arousal and intrusion in one study (Fesler 1991) and arousal and avoidance in the other (R. D. Clark et al. 1999), whereas topiramate (15.5–500 mg/day) was most effective in reducing symptoms of intrusion, particularly nightmares and flashbacks (Berlant and van Kammen 2002). The largest placebo-controlled trial of an anticonvulsant to date found no difference between tiagabine, dosed up to 16 mg per day, and placebo in 232 patients in a 12-week multicenter trial (Davidson et al. 2007). In a small placebo-controlled trial of lamotrigine (200–500 mg per day) in 15 outpatients (Hertzberg et al. 1999), a response rate of 50% was noted with lamotrigine, compared with a placebo response rate of 25%.

Other Treatments

Antipsychotics

One placebo-controlled monotherapy trial of olanzapine has been published (Butterfield et al. 2001), in which 15 subjects were randomized 2:1 to treatment with olanzapine (up to 20 mg/day) or placebo. No differences were observed between the treatments, although olanzapine was associated with greater weight gain. It is difficult to interpret these findings in this small sample, especially given the high placebo response rate (60%). Other reports of antipsychotics are based on augmentation therapy in SSRI partial responders. Four placebo-controlled studies, mainly as augmentation, have found superior efficacy for low-dose risperidone (Bartzokis et al. 2005; Hamner et al. 2003; Monnelly et al. 2003; Reich et al. 2004) and olanzapine (M. B. Stein et al. 2002). In the Monnelly study, particular benefit was noted for irritability and in the Hamner study, psychotic symptoms were relieved. These antipsychotic studies in aggregate comprised 155 patients.

Prazosin and Guanfacine

Raskind et al. (2003) reported encouraging results for intractable PTSD-related nightmares in a placebo-controlled crossover study of prazosin, an α_1-adrenergic antagonist, at doses of up to 10 mg/day. The investigators have confirmed their initial findings in a second and larger placebo-controlled, double-blind augmentation trial conducted in combat veterans, using doses of up to 15 mg daily; benefits were most apparent on nightmares and sleep quality, but the drug also produced greater global improvement (Raskind et al. 2007). One possible mechanism of action may lie in the ability of prazosin to reduce the output of corticotropin-releasing hormone. Suppression of nightmare-

generating non–rapid eye movement stage 1 sleep may be another explanation for this intriguing finding. Standing in contrast is a negative placebo-controlled study of the α_2-adrenergic agonist guanfacine in patients who, unlike those in the prazosin studies, were not preselected for having troublesome nightmares (Neylan et al. 2006).

Other Drugs

Given the prevalence of comorbid depression with PTSD and the effectiveness of triiodothyronine (T_3) augmentation in some individuals with treatment-refractory depression, it is possible that T_3 augmentation also may be of benefit in PTSD. Five subjects with PTSD currently taking an SSRI were treated with open-label T_3 (25 μg/day) for 8 weeks (Agid et al. 2001). Improvement was noted as early as 2 weeks, and by the end of treatment, four of the five subjects showed at least partial improvement in depressive symptoms and hyperarousal. The mechanism for these effects is unknown, and further controlled studies of this augmentation strategy are therefore needed. Cyproheptadine, an antihistaminic drug, was no more effective than placebo for nightmares over 2 weeks in a series of 69 combat veterans with PTSD (Jacobs-Rebhun et al. 2000). The naturally occurring compound inositol was ineffective in a small placebo-controlled trial (Kaplan et al. 1996).

ACUTE STRESS DISORDER AND THE IMMEDIATE AFTERMATH OF TRAUMA

Acute stress disorder (ASD) is characterized by the development of a constellation of symptoms shortly after a traumatic event and includes symptoms of dissociation and intrusive recollections, avoidance, and hyperarousal. These symptoms persist for 2–28 days following the trauma and cause significant distress and/or impairment. If the condition persists beyond 1 month, the individual usually qualifies for a diagnosis of PTSD. ASD was first included in the diagnostic nosology in DSM-IV, and little is known about the pharmacotherapy of this disorder. As noted earlier, it has been suggested that early intervention for trauma survivors might help to alter the course of PTSD, and this would imply early identification and treatment of those with or at risk for ASD.

The effects of open-label treatment with risperidone have been reported in four inpatient survivors of physical trauma with ASD; this drug showed possible benefit in flashback symptoms (Eidelman et al. 2000). A controlled pilot study assessed the effects of low-dose imipramine compared with choral hydrate in 25 pediatric burn patients with ASD (Robert et al. 1999a). After 1 week of treatment, 38% of the subjects responded to treatment with placebo, compared with 83% to imipramine, with an earlier report noting reduction in intrusion and hyperarousal symptoms (Robert et al. 1999b). Another study evaluated the effects of β-adrenergic blockade in reducing subsequent PTSD following acute trauma (Pitman et al. 2002). Within 6 hours of the trauma, subjects were treated with either propranolol (*n* = 18; 40 mg qid) or placebo (*n* = 23) for 10 days, followed by a 9-day taper period. One month after the trauma, PTSD was noted in 30% of the placebo group compared with 10% of the propranolol group. At 3-month follow-up, physiological arousal was assessed using personal script-driven imagery of the event, and 43% of the placebo group were physiological responders compared with 0% of the propranolol group. Although the dropout rate was higher with propranolol (7 of 18; 39%) than with placebo (3 of 23; 13%), these findings suggest that acute treatment with β-adrenergic-blocking agents may be effective in preventing the later development of PTSD, but further studies are needed. In one study of temazepam versus placebo for ASD or subthreshold PTSD, coupled with at least moderate sleep disturbance, there was no advantage for the drug, either during treatment or at follow-up 6 weeks posttrauma (Mellman et al. 2002). Two promising studies have found greater long-term benefit for short-term hydrocortisone versus placebo in high-risk subjects recovering from septic shock and from cardiac surgery (Schelling et al. 2006). In subpopulations with critical illness–related corticosteroid insufficiency, this might be an attractive treatment approach for preventing PTSD. One limitation of the authors' work, however, has been the absence of baseline PTSD ratings before administration of hydrocortisone.

CBT has been extensively studied in PTSD and shows efficacy in most cases (Bisson and Andrew 2005). Exposure is regarded as the key therapeutic principle in the numerous variants of CBT. Modest preservation of gains is found at long-term follow-up (Bradley et al. 2005), but much pathology remains. For this reason, it is unfortunate that there are almost no trials, either long or short term, combining CBT with drugs. Shortened forms of CBT appear to be effective for acute PTSD-like states, with persistence of gain at 4-year follow-up (Bryant et al. 1998, 2003).

CONCLUSION

Twenty years ago, few would have thought that one class of drugs, the SSRIs, which were all introduced initially for depression, would have established primacy in five of the six major anxiety disorder categories. Their position is based on solid category 1 randomized, controlled trial evidence, and they are now first-line drugs for treatment of these disorders. To the extent that studies have been conducted, SSRIs also offer some protection against relapse. However, they are not 100% successful, they carry some limiting side effects, and they may require supplementation with, or substitution by, drugs from other categories. We have reviewed what is known about these other drugs and expect further progress in the pharmacotherapy of anxiety, with both established drugs and novel categories (e.g., corticotropin-releasing hormone antagonist). Among many unexplored areas, we need to know more about the treatment of resistant anxiety disorders and comorbid anxiety disorder and the comparative efficacy, or contribution, of pharmacotherapy and psychosocial treatment in anxiety.

The rationale for using drugs rests, in part, on the broad-based evidence that vulnerability to each of the anxiety disorders includes shared and/or unique genetic risk factors, which usually coexist with environmental factors in respect of explaining variance. High trait neuroticism is a genetic risk factor for internalizing disorders as a whole and for comorbidity among the anxiety disorders and depression (Hettema et al. 2006). A diagnostically nonspecific genetic vulnerability may underlie fear proneness and amygdalar hyperreactivity (Hariri et al. 2005). Family and twin studies, as well as other types of studies, support genetic risk factors for generalized anxiety, panic disorder, phobias, and OCD (Hettema et al. 2001; Westenberg et al. 2007) and social anxiety disorder (Mathew and Ho 2007), for which some candidate genes are beginning to emerge. For PTSD, the evidence suggests a role for unique and shared genetic effects (Chantarujikapong et al. 2001; True et al. 1993), including common genetic liability for PTSD and major depression (Koenen et al. 2008). While detailed consideration of genetics goes beyond the scope of this chapter, it is of considerable interest to note the findings of M. B. Stein et al. (2006) and Denys et al. (2007), for example, that drug response in social anxiety disorder and OCD, respectively, may be related to genetic polymorphisms. These exciting findings may herald a time when we can more effectively individualize pharmacotherapy for anxiety.

Chapter 57. Treatment of Agitation and Aggression in the Elderly

TREATMENT OF AGITATION AND AGGRESSION IN THE ELDERLY: INTRODUCTION

Severe agitation—restlessness, wandering, or screaming—may accompany late-life psychosis or dementia, with particularly high prevalence rates in nursing homes. Aggression and assaultiveness may also occur as a consequence of the delusions or hallucinations of late-life psychosis from dementia, depression, or a combination of these factors. Behavioral and psychiatric symptoms develop in as many as 60% of community-dwelling dementia patients (Lyketsos et al. 2000; Ryu et al. 2005; Tractenberg et al. 2003; Wragg and Jeste 1988). The lifetime risk of behavioral complications of dementia approaches 100% (Lyketsos et al. 2000). Rates of physical aggression range from 11% to 46% among community-dwelling dementia patients and from 31% to 42% among patients in institutional settings (Billig et al. 1991; Brodaty et al. 2003; Cohen-Mansfield et al. 1995; Peabody et al. 1987; Wragg and Jeste 1988; Zimmer et al. 1984). The etiology of agitation and aggression in late-life psychosis or dementia is unknown, although environmental and biological factors, such as drug toxicity, medical illness, pain, frustration, loneliness, reduced sensory input, new surroundings, diminished nutritional status, and altered central nervous system (CNS) function, alone or in combination, may play important roles (Mintzer and Brawman-Mintzer 1996).

In recent years, researchers and clinicians have begun to categorize disruptive behavioral syndromes according to associated etiology, as agitation and aggression of 1) psychosis, 2) dementia with psychosis, and 3) nonpsychotic dementia (Jeste et al. 2006). At present, there are no specific diagnostic categories of "psychosis with dementia" or "dementia-related agitation," so that all treatments are "off label." Psychotic and nonpsychotic patients have been mixed together in clinical trials, which may have confused the outcomes and clinical recommendations. A distinct category of "psychosis of Alzheimer's disease and related dementia" may improve research into late-life agitation and aggression (Jeste and Finkel 2000).

No drugs have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of persisting psychosis, agitation, or aggression associated with dementia. Nevertheless, despite only modest benefits and frequent warnings about adverse effects and inappropriate use, antipsychotic drugs continue to be used as first-line agents. An increasing number of other medication classes, including anticonvulsants, antidepressants, and cognitive enhancers, are also being used as second-line choices for management of agitation and aggression in dementia that cannot be managed without medication (Docherty et al. 1998; Jeste et al. 2008; Kindermann et al. 2002; Raivio et al. 2007; Salzman 2000; Salzman and Tune 2001; Salzman et al. 2008; Small et al. 1997).

ANTIPSYCHOTIC TREATMENT

First-Generation (Conventional, Typical) Antipsychotics

Before the second-generation (atypical) antipsychotics, with their superior side-effect profiles, became available, first-generation antipsychotics (FGAs; sometimes called conventional or typical antipsychotics), especially haloperidol, were the mainstay of treatment of late-life agitation. Extrapyramidal side effects (EPS), however, are common with haloperidol, especially in the elderly,

limiting its usefulness. Tardive dyskinesia, a late-appearing EPS, develops more rapidly and at lower antipsychotic doses in elderly patients than in younger ones (Caligiuri et al. 1999; Jeste et al. 1999; Karson et al. 1990; Lieberman et al. 1984; Saltz et al. 1989). Tardive dyskinesia is also more common in patients with evidence of cortical atrophy and in dementia patients (Sweet and Pollock 1992). When antipsychotics are discontinued, tardive dyskinesia symptoms are less likely to disappear in older patients than in younger adults (Smith and Baldessarini 1980; Yassa et al. 1984), although the symptoms may not increase in severity (Yassa et al. 1992). These concerns regarding tardive dyskinesia and other EPS have contributed to the switch in clinical preference for the newer antipsychotic drugs.

Second-Generation Antipsychotics

Second-generation antipsychotics (SGAs; sometimes called atypical antipsychotics) have replaced conventional antipsychotics as the first-choice treatment for agitation and aggression in the elderly. As a class, these newer antipsychotics carry a lower risk of EPS and tardive dyskinesia. Although pharmacokinetic data are not available for all of the newer SGAs, studies of risperidone indicate that clearance of risperidone and its 9-hydroxy metabolite does not decline with age, whereas clearance of quetiapine is reduced with increasing age (Jaskiw et al. 2004; Maxwell et al. 2002).

SGAs are as effective as FGAs for treating agitation and aggression, with or without associated psychosis (Ballard and Waite 2006; Sink et al. 2005). Ballard and Waite (2006), for example, found a significant improvement in aggression with risperidone and olanzapine compared with placebo and a significant improvement in dementia-associated psychosis among risperidone-treated patients. These observations have been supported by numerous other studies. Katz et al. (1999) reported the superiority of risperidone compared with placebo for the treatment of agitation in Alzheimer's disease. Street et al. (2000) reported that olanzapine was superior to placebo for agitation associated with Alzheimer's disease. Meehan et al. (2002) studied acute treatment of agitation with intramuscular olanzapine in 272 inpatients or nursing home residents with Alzheimer's disease and/or vascular dementia. Patients were given up to three injections of olanzapine (2.5 mg or 5.0 mg), lorazepam (1.0 mg or 0.5 mg), or placebo and assessed within a 24-hour period. Olanzapine was found to be superior to placebo in treating agitation at 2 hours and 24 hours. Adverse events were not significantly different between groups. Aripiprazole was also reported to be superior to placebo for treatment of psychosis of Alzheimer's disease in outpatients (Laks et al. 2006).

Not all studies of SGAs have reported positive results, however. In a placebo-controlled multicenter trial comparing quetiapine and haloperidol versus placebo for psychosis associated with dementia, Tariot et al. (2006) reported no benefit of either active treatment, with one secondary measure of agitation suggesting benefit. This led to a subsequent placebo-controlled multicenter trial of quetiapine at fixed dosages (100 mg/day and 200 mg/day), which found overall superiority for quetiapine compared with placebo in the management of agitation (Zhong et al. 2006, 2007). Ballard and Waite (2006) conducted a placebo-controlled trial of quetiapine versus rivastigmine in which no benefit of either treatment was observed on behavioral outcomes; cognition worsened in the quetiapine group, a worrisome result that has not been seen in any other study of quetiapine.

The Clinical Antipsychotic Trials of Intervention Effectiveness—Alzheimer's Disease (CATIE-AD) addressed the relative effectiveness of commonly used atypical antipsychotics (Schneider et al. 2006). Outpatients with Alzheimer's disease and psychosis, aggression, or agitation were randomly assigned to treatment with olanzapine (mean dosage ≅ 5 mg/day), quetiapine (mean dosage ≅ 50 mg/day), risperidone (mean dosage ≅ 1 mg/day), or placebo. No conventional antipsychotic was included in the study because of concerns about tardive dyskinesia. The primary measure of effectiveness was time to all-cause discontinuation; secondary measures addressed time to discontinuation due to lack of efficacy, significant safety concerns, or death, as well as improvement in Clinical Global Impression Scale Change scores. There was no significant difference among the

drugs in the primary outcomes, although time to discontinuation due to lack of efficacy was longer with olanzapine and risperidone versus quetiapine or placebo. Conversely, time to discontinuation due to adverse events or drug intolerability was longer for all active treatments than for placebo. The CATIE-AD trial, therefore, confirmed the modest efficacy of atypical antipsychotic drugs as a class.

Meta-analytic reviews also suggest that the overall efficacy of SGAs for treatment of agitation and aggression is modest, as is the difference between active drug and placebo. Overall response rates in CATIE-AD ranged from 48% to 65% with active treatment versus 30%–48% with placebo, showing an incremental treatment benefit of about 18% for active drug over placebo (Schneider et al. 2006).

Studies comparing SGAs with FGAs have reported significantly greater efficacy for second-generation agents than for first-generation ones (Suh et al. 2004), and in all studies, the FGAs were associated with more EPS than the SGAs (Chan et al. 2001; De Deyn et al. 1999; Suh et al. 2004). The CATIE-AD study, lacking an FGA arm, could not add to these observations.

Side Effects of Antipsychotic Drugs

In addition to modest efficacy, reports of serious side effects other than EPS and tardive dyskinesia have raised concerns regarding the use of antipsychotics as first-line treatments for agitation or aggression, with or without psychosis, in elderly populations. An initial report indicating an increased risk of cerebrovascular adverse events (CVAEs; e.g., stroke, transient ischemic attack [TIA], death) in male nursing home residents older than 85 years who were treated with risperidone (Wooltorton 2002) led to further investigation. Similar suggestive evidence was reported for olanzapine and ultimately for other SGAs (Kryzhanovskaya et al. 2006; Percudani et al. 2005; Wooltorton 2004). Taken together, these observations of increased CVAEs in elderly individuals receiving SGAs stimulated an examination of all studies, which supported concerns regarding a possible increased risk of CVAEs when either of these drugs is given to elderly patients with dementia. Data from 11 olanzapine or risperidone studies collectively suggested that 2.2% of drug-treated subjects experienced CVAEs, compared with 0.8% of placebo-treated subjects. The combined relative risk was 2.7. Ballard and Waite (2006) concluded that despite the modest efficacy of these drugs, the significance of the adverse events dictates that "neither risperidone nor olanzapine should be used routinely to treat dementia patients with aggression or psychosis unless there is marked risk or severe distress."

In 2003, the FDA issued a black box warning regarding a possible increased risk of CVAEs associated with use of atypical antipsychotics in older adults with dementia. The warning was eventually extended to include aripiprazole, olanzapine, and risperidone. The death rate in clinical trials was 3.5% with SGAs versus 2.3% with placebo, leading the FDA to impose a black box warning for all SGAs. Studies examining large public databases (Ballard and Waite 2006; Schneider et al. 2006) have found similar rates of death among elderly people receiving FGAs (Schneeweiss et al. 2007; Wang et al. 2005).

The FDA warning has generated considerable controversy. Some researchers, examining the data on which the FDA's warning was based, have become concerned that methodological faults in many of the studies may have compromised the meta-analyses and led to an overly harsh interpretation of the data and an unwarranted concern for safety. Some studies failed to find an increase in death rate or incidence of CVAEs. For example, Herrmann et al. (2004), as well as Haupt et al. (2006) and Gill et al. (2005), found no significant increase in the risk of ischemic stroke with either FGAs or SGAs or among those receiving SGAs compared with FGAs. The American College of Neuropsychopharmacology has issued a White Paper (Jeste et al. 2008) concluding that further research data are needed to clarify the ongoing significance, if any, of increased development of CVAEs. An expert consensus conference held in 2006 (Salzman et al. 2008) essentially made the same point.

Most recently, a retrospective study of 254 very frail patients with dementia (mean age = 86 years)

from seven nursing homes and two hospitals in Finland found that neither SGAs nor FGAs increased mortality (the use of SGAs actually should lower the risk of mortality) (Raivio et al. 2007).

Clinicians currently struggle with a difficult treatment dilemma when confronted with an elderly patient with dementia who is possibly psychotic and whose behavior is characterized by extreme agitation and/or aggression that cannot be controlled without medications. The essential conclusion of the CATIE-AD study, and a sensible statement about the role of antipsychotics (Jeste et al. 2008; Salzman et al. 2008; Sink et al. 2005), was that on average, patients receive modest benefit without being harmed: these are the patients for whom continued therapy is rational. The following clinical conclusions appear to be warranted at this time:

1. Recognizing that the use of antipsychotic drugs to treat agitation or aggression is "off label," clinicians must be certain that the behavior cannot be managed nonpharmacologically and that the severity of the disruptive behavior warrants the selection of this class of drugs. If an FGA such as haloperidol is selected, doses should be kept low to minimize the likelihood of developing EPS.
2. SGAs are still preferred to FGAs because of the lower likelihood of EPS and tardive dyskinesia.
3. Clinicians should confer with the patient's family or significant others regarding the use of these drugs and should attempt to obtain some form of informed consent, balancing the possible risk of using these medications against the likelihood of worsening behavior and clinical status without such treatment.
4. Clinicians should follow these patients closely for early warning signs of a CVAE.

NON-ANTIPSYCHOTIC TREATMENT

A growing body of clinical experience, research, and anecdotal reports suggests that agents such as trazodone, anticonvulsants (mood stabilizers), buspirone, serotonergic antidepressants, and cognitive enhancers may help manage a variety of agitated behaviors refractory to more conventional treatment. These drugs, however, are ineffective in treating symptoms of psychosis.

Benzodiazepines

Although benzodiazepines are quite widely used in this population, there have been no studies of benzodiazepine treatment of agitation or aggression in nearly a decade. Most of the older studies were not placebo controlled, but they nonetheless suggested that on average, agitation could be reduced with short-term benzodiazepine therapy (Loy et al. 1999). For example, Coccaro et al. (1990) compared oxazepam (10–60 mg/day) with low-dose haloperidol in patients with mixed dementia diagnoses. Five percent of patients in the benzodiazepine group improved, compared with 24% of those in the haloperidol group, a difference that was not statistically significant, perhaps because of the small sample size. Christensen and Benfield (1998) compared alprazolam (0.5 mg twice daily) with haloperidol (0.6 mg/day) in a crossover study. Adverse events were not significantly different between groups. The dosages of both agents used in this study were probably too low to expect an effect, and none was seen. Meehan et al. (2002) noted that intramuscular lorazepam 1.0 mg or 0.5 mg was superior to placebo at 2 hours but not at 24 hours.

Possible side effects of benzodiazepines given to elderly individuals include ataxia, falls, confusion, anterograde amnesia, sedation, light-headedness, and tolerance and withdrawal syndromes (Patel and Tariot 1995). This profile, along with the scant evidence of efficacy, suggests that use of benzodiazepines for agitation should be time limited or on an as-needed basis, with chronic use only for those patients in whom other agents have proven ineffective. Drugs with simpler metabolisms and relatively short half-lives, such as lorazepam, are always preferred.

Anticonvulsants (Mood Stabilizers)

Although Chambers et al. (1982) reported no benefit of carbamazepine in a crossover study in 19 patients with agitation, most subsequent studies suggest that anticonvulsants are modestly helpful for controlling agitation and aggression in elderly individuals with dementia. In a placebo-controlled

crossover study in 25 agitated dementia patients, Tariot et al. (1994) reported improvement with carbamazepine. This was supported by a confirmatory parallel-group study of 51 patients in which the mean daily dosage was 300 mg (Tariot et al. 1998). Carbamazepine was well tolerated in both studies; sedation and ataxia were the most common side effects (Tariot et al. 1998, 2002). Another small (*n* = 21) placebo-controlled study of carbamazepine (400 mg/day) reported modest benefit. Adverse events were reported as mild (Olin et al. 2001). Despite these preliminary findings, there is a relative dearth of evidence of efficacy from controlled clinical trials. Given the high risk of drug–drug interactions with carbamazepine and the frequent side effects seen in other populations (including rashes, sedation, hematological abnormalities, hepatic dysfunction, and altered electrolytes), carbamazepine should not be considered a first-choice treatment in this population.

Valproic acid, and its enteric-coated derivative divalproex sodium, has been the subject of a number of case reports or case series in patients with dementia and agitation, in which about two-thirds of patients with dementia and agitation have been described as clinically improved. The first randomized, placebo-controlled, parallel-group study of valproate was conducted as a precursor to a larger multicenter trial (Porsteinsson et al. 2001); a secondary measure of agitation showed improvement that was also seen in an open-label extension (Porsteinsson et al. 2003). Side effects seen with valproate included sedation, gastrointestinal distress, and ataxia, as well as the expected decrease in average platelet count (about 20,000/mm^3). A small placebo-controlled crossover study of valproate used for aggressive behavior found no benefit on primary measures of aggression (Sival et al. 2002). There were no drug–placebo differences in rates or types of adverse events. A 6-week randomized, placebo-controlled multicenter study of divalproex sodium in 172 nursing home residents with dementia and agitation who also met criteria for secondary mania used a target dosage of 10 mg/kg/day for 10 days (Tariot et al. 2001b). There was a high dropout rate (*n* = 100 completers), with 19 divalproex sodium–treated patients (22%) and 3 placebo-treated patients (4%) withdrawing from the study because of adverse events, primarily somnolence (typically occurring at daily dosages ≥15 mg/kg).There were no significant drug–placebo differences in change in manic features, although a significant drug effect on agitation was seen. Sedation occurred in 36% of the drug group versus 20% of the placebo group, and mild thrombocytopenia occurred in 7% of the drug group versus none of the placebo-treated patients. There were no other significant drug–placebo differences in adverse effects. The results from this trial were used to amend prescribing information by cautioning against the use of similar high doses and/or titration rates in the elderly. The largest (*n* = 153) placebo-controlled trial prospectively addressing agitation, conducted by the Alzheimer's Disease Cooperative Study, found no benefit from divalproex (Tariot et al. 2005). In a comprehensive review, Sink et al. (2005) likewise failed to find benefit for divalproex, and they noted mixed results regarding the efficacy of carbamazepine in patients with dementia. A Cochrane review of valproate for agitation in dementia (Lonergan et al. 2004) concluded that low-dose valproate was ineffective and that high-dose valproate was associated with an unacceptable rate of adverse effects.

There are no placebo-controlled studies of lamotrigine, gabapentin, or topiramate in the treatment of behavioral symptoms in dementia. Despite the absence of controlled studies, however, anticonvulsants are used in clinical practice when other drug treatments fail or are poorly tolerated. The greatest amount of clinical data are available for gabapentin, with almost all reports noting improvement in a majority (but not all) of the subjects. Dosages used ranged from 200 to 1,200 mg/day (Alkhalil et al. 2004; Goldenberg et al. 1998; Herrmann et al. 2000; Moretti et al. 2003; Roane et al. 2000). A review of case reports described worsening of behavior in Lewy body dementia patients who received gabapentin (Rossi et al. 2002). A small retrospective review of topiramate found that agent modestly helpful for aggressive behavior in dementia (Fhager et al. 2003). A single letter to the editor reported the usefulness of lamotrigine for the treatment of aggression in dementia (Devarajan and Dursun 2000).

In an effort to develop more innovative clinical trial designs, as well as to address the public health

significance of psychopathology in Alzheimer's disease, the Alzheimer's Disease Cooperative Study organized the first multicenter trial addressing secondary prevention of psychopathology in Alzheimer's disease (Tariot et al. 2002). This multicenter study is examining whether valproate therapy can delay, attenuate, or prevent the emergence of agitation or psychosis in patients lacking these features at baseline. The design incorporates traditional measures of illness progression as secondary outcomes, based on the potential for neuroprotective effects of chronic administration, and may contribute to improved understanding of mechanisms of action of valproate therapy via use of biological markers selected for their relevance to mechanism of action as well as pathobiology of Alzheimer's disease. The study has completed enrollment and will end in early 2009.

Serotonergic Drugs

Sink et al. (2005) found little overall evidence of efficacy for antidepressants in the treatment of neuropsychiatric symptoms other than depression. However, because depression, including irritability, is commonly seen in people with dementia, serotonergic antidepressants are often used in their treatment.

The antidepressant drug trazodone has been reported to be effective in treating agitation and severely disruptive behavior (Greenwald et al. 1986; Nair et al. 1973; Pinner and Rich 1988; Simpson and Foster 1986; Tingle 1986), although these studies did not distinguish between psychotic and nonpsychotic patients. Extensive clinical experience suggests that trazodone is effective at dosages of 50–200 mg/day, with few side effects other than sedation. The mechanism of trazodone's effect is unknown. There have been two double-blind, controlled studies of trazodone in the treatment of dementia-associated agitation. The first was a brief crossover study in only 28 patients, comparing trazodone at a mean dosage of 220 mg/day with haloperidol at a mean dosage of 2.5 mg/day (Sultzer et al. 1997). Agitation improved equally in both drug groups, with better tolerability seen in the trazodone group. The Alzheimer's Disease Cooperative Study reported negative results for all active treatments in a multicenter outpatient study contrasting trazodone, haloperidol, placebo, and caregiver training (Teri et al. 2000). Although there is negative as well as positive evidence of trazodone's efficacy, clinical experience suggests that trazodone is often extremely helpful as an add-on medication when antipsychotics or other drugs alone cannot control disruptive behavior. Priapism is a rare side effect of trazodone in elderly men.

Selective serotonin reuptake inhibitor (SSRI) antidepressants may also have modest antiagitation properties in elderly patients with dementia (Burke et al. 1997; Swartz et al. 1997). Citalopram (Kim et al. 2000; Pollock et al. 2002) and sertraline (Kaplan 1998), in particular, have demonstrated efficacy. In a double-blind study, citalopram was found to be effective, and superior to perphenzine, in treating behavioral disturbances in hospitalized elderly patients with dementia (Pollock et al. 2002). Sertraline in combination with a cognitive-enhancing medication (donepezil) was reported to decrease agitation, although a fulminant chemical hepatitis developed in one patient, necessitating discontinuation (Verrico et al. 2000). In contrast to these positive reports, Olafsson et al. (1992) failed to show the effectiveness of fluvoxamine in the treatment of behavioral disruption in elderly patients with dementia. One review suggested that when antipsychotics cannot be used, SSRIs should be considered first-line treatment (Burke et al. 1997), especially for verbal aggression (Ramadan et al. 2000). Further research of the antiagitation properties of the SSRIs is essential, however, because these antidepressants also tend to be activating and may actually increase agitation, especially in the late stages of a dementing illness.

Buspirone, a nonbenzodiazepine antianxiety agent with effects at serotonin receptors, was reported to be effective in controlling disruptive behavior in older patients in one study (Colenda 1988) but not in another (Strauss 1988). No randomized, placebo-controlled, double-blind studies of buspirone have been conducted, and available studies were small in size. There is insufficient evidence to inform about dosing, titration, safety, tolerability, and efficacy. A small (n = 20) single-blind, placebo-

controlled trial reported improvement on measures of aggression, but only 60% of the 20 subjects completed that study (Levy et al. 1994). In a crossover study (*n* = 10) comparing buspirone with trazodone, Lawlor (1994) found no relative benefit of buspirone. Cantillon et al. (1996) compared buspirone 15 mg/day versus haloperidol 1.3 mg/day in a nursing home population with Alzheimer's disease (*n* = 26); they reported no significant benefit of either drug. Even when buspirone is effective, disruptive behavior may not decrease for 1 or 2 weeks at full therapeutic doses. Side effects are modest, although one elderly patient with dementia experienced oral dyskinesia that persisted for at least 4 months after symptom onset (Strauss 1988). An occasional patient may become more agitated. Research studies have not yet compared buspirone's effect with that of placebo or other drugs for treating agitation. The average total daily dosage range is 20–80 mg in divided doses.

Beta-Blockers

β-Blockers, given at low dosages (10–100 mg/day), have been used to reduce agitated and assaultive behavior in elderly patients (Greendyke et al. 1984; Petrie and Ban 1981; Sky and Grossberg 1994). Not all studies of β-blockers have yielded positive findings, however (Risse and Barnes 1986; Weiler et al. 1988). Most evidence is derived from older reports in patients with nonspecific diagnoses (Tariot et al. 1995). Shankle et al. (1995) reported decreased aggression in 8 of 12 patients treated with low doses of propranolol (30–80 mg/day). Side effects of note include bradycardia, hypotension, worsening of congestive heart failure, and asthma. β-Blockers should be used only sparingly for this purpose. Furthermore, these drugs can be given only to those elderly patients without cardiovascular disease and chronic obstructive pulmonary disease (particularly asthma). Typical side effects include sedation, orthostatic hypotension, and decreased cardiac output.

Hormones

There are no rigorous studies of either estrogenic or antiandrogenic approaches, although roughly a dozen published anecdotes exist (Rosenquist et al. 2000). The available evidence suggests occasional benefit for hormonal agents, but this is unproven. A single case report (Kyomen et al. 1991) noted that estrogen (diethylstilbestrol 1 mg/day or conjugated estrogen 0.625 mg/day) reduced the number of incidents of physical aggression, but not of verbal aggression or physical or verbal repetitive behaviors, in elderly male patients with dementia. Medroxyprogesterone has been reported to rapidly and safely treat sexual acting-out behavior in elderly men with dementia (Cooper 1987).

Cognitive-Enhancing Drugs

Cholinergic Agents

As summarized by Cummings (2000), there is increasing evidence that cholinergic agents, especially cholinesterase inhibitors, may have modest behavioral benefits in some patients with dementia. However, most data come from multicenter studies primarily addressing cognitive or global outcomes, using behavioral measures as secondary outcomes.

A prospective clinical trial of metrifonate versus placebo found modest average reductions in neuropsychiatric symptoms, as assessed with the Neuropsychiatric Inventory (NPI), in the drug group versus the placebo group (Morris et al. 1998). A retrospective analysis of two 26-week double-blind, placebo-controlled multicenter trials of metrifonate found a behavioral effect size of 15%, with significant improvement observed on measures of agitation/aggression and aberrant motor behavior as well as hallucinations, dysphoria, and apathy (Cummings et al. 2001; Raskind and Risse 1986).

In a 5-month study of galantamine, Tariot et al. (2000) showed reduced symptoms of cognitive and attentional dysfunction on drug versus placebo in outpatients who generally lacked psychopathology at baseline. In a placebo-controlled trial of donepezil in nursing home residents with probable Alzheimer's disease complicated by behavioral symptoms, there was no evidence of improved

behavior on a global measure, although a secondary analysis showed some evidence of reduced agitation (Tariot et al. 2001a). Another study of donepezil in mild to moderate Alzheimer's disease found overall improvement, with modest improvement in behavioral symptoms (Holmes et al. 2004). A subsequent study, however, failed to find improvement in behavioral symptoms with rivastigmine (Ballard and Waite 2006). There appears to be no reliable evidence for the therapeutic effect of this drug on psychosis or behavioral symptoms of dementia and related behavioral disruption. The cholinesterase inhibitors donepezil, rivastigmine, and galantamine have each been reported to reduce restlessness in a small number of elderly individuals with Lewy body dementia (Herrmann et al. 2004; Maclean et al. 2001; Skjerve and Nygaard 2000).

Memantine

Memantine, a noncompetitive inhibitor of *N*-methyl-D-aspartate (NMDA) receptors approved by the FDA for treatment of moderate to severe Alzheimer's disease, has been examined in several multicenter trials, none addressing behavior as a primary objective. A placebo-controlled study of memantine 10 mg/day in patients with severe dementia showed no benefit on the single behavior item that was used (Winblad and Poritis 1999). A subsequent placebo-controlled study of memantine 20 mg/day also did not find significant behavioral benefit (Reisberg et al. 2003). However, a study in which memantine or placebo was administered to patients already receiving donepezil found significant benefit from memantine on behavior (Cummings et al. 2006a, 2006b; Tariot et al. 2004). In a meta-analysis, Sink et al. (2005) found that cholinesterase inhibitors had a small but statistically significant benefit for behavioral symptoms, whereas memantine had no significant benefit. Trinh et al. (2003) also reported slight overall benefit from cholinesterase inhibitors in patients with mild to moderate Alzheimer's disease. More recently, modest behavioral benefits of memantine have been reported (Swanberg 2007; Winblad and Poritis 1999; Winblad et al. 2007), including data from unpublished trials. Memantine added to donepezil also has been shown to have modest benefit for behavioral disruption in Alzheimer's disease (Tariot et al. 2004). More research is needed on the use of these drugs for treatment of dementia-associated agitation.

CONCLUSION

Good clinical care of the agitated and/or aggressive elderly patient with dementia requires careful appraisal of factors that may be contributing to the disruptive behavior. Special attention should be paid to recent changes in medical status, treatment with nonpsychiatric medications, and alterations in the environment (Jeste et al. 2008; Salzman et al. 2008). When psychiatric medications become necessary, clinicians now may choose among several classes of psychotropic agents: antipsychotic drugs, mood stabilizers, and serotonergic antidepressants. Available data would suggest that antipsychotic agents are still the first-choice class of drugs, especially for the most severely agitated and aggressive elderly person. This class of drugs, however, carries a potential increased risk of side effects, including extrapyramidal symptoms, cerebrovascular events (including stroke), and possibly premature death. Clinicians must endeavor to use these medications carefully, therefore, monitoring patients closely and informing family members (or significant responsible individuals) of these risks. Initial doses should be modest, with careful dose increments, following the geriatric maxim "Start low and go slow." Other recommended classes of psychotropic drug treatment, in order of preference, are mood stabilizers, serotonergic antidepressants, and cognitive enhancers. These medications are less reliably effective but lack the side effects of antipsychotic drugs. Clinical choice depends on the physical health, prior drug response, and vulnerability to side effects of the elderly individual.

Future research will continue to elucidate the risks versus benefits of different classes of psychotropic drugs while also developing nonpharmacological approaches for the treatment of the common yet serious disruptive behavioral problems associated with dementia.

Chapter 58. Treatment of Substance-Related Disorders

TREATMENT OF SUBSTANCE-RELATED DISORDERS: INTRODUCTION

Drugs that produce substance use disorders all activate the brain reward system, but each class of drugs activates the system by a different pharmacological mechanism. Thus, this chapter is organized according to pharmacological class. The emphasis is on pharmacotherapy, but all treatment using medications should be accompanied by counseling or psychotherapy according to the patient's needs. Medication combines very well with psychotherapy, including self-help groups such as Alcoholics Anonymous (AA). The majority of patients also have an additional mental disorder (besides the addictive disorder) such as depression, anxiety, or bipolar disorder. These comorbidities require specific treatment including medication and psychotherapy. The best treatments for addiction complicated by additional psychiatric disorders are delivered in an integrated fashion, preferably from the same therapist. All psychiatrists should be able to manage substance use disorders, especially those that co-occur with other psychiatric diagnoses.

ALCOHOL

The 12-month prevalence of alcohol use disorders in the United States in the most recent epidemiological survey was 7.35%, and combined with other drug use disorders the total was more than 8.4% (Compton et al. 2007). Alcohol is the number one substance chosen by both adults and teenagers. The annual loss of life for all causes, but often through accidents, is over $185 billion per year. In a 2005 survey among twelfth-grade students, 53% had used alcohol in the past 30 days and 34% had been drunk during the same period (Johnston 2006). As with all substance use disorders, the best treatments involve a combination of psychotherapy and pharmacotherapy. A variety of medications have been used at the important stages of alcohol use disorder treatment. The first stage is detoxification, which means clearing of the alcohol from the body. After detoxification, the relapse prevention stage should be continued for months or even years.

Alcohol Detoxification

Detoxification involves the clearing of alcohol from the body and the readjustment of all systems to functioning in the absence of alcohol. The alcohol withdrawal syndrome at the mild end may include only headache and irritability, but about 5% of alcoholic patients have severe withdrawal symptoms manifested by tremulousness, tachycardia, rapid respiration, and even seizures. The presence of malnutrition, electrolyte imbalance, or infection increases the possibility of cardiovascular collapse.

Significant progress has been made in establishing safe and effective medications for alcohol withdrawal. Pharmacotherapy with a benzodiazepine is the treatment of choice for the prevention and treatment of the signs and symptoms of alcohol withdrawal. Many patients, however, detoxify from alcohol dependence without specific treatment or medications. It is difficult to determine accurately which persons require medication for alcohol withdrawal. Clinicians should learn to use a formal alcohol withdrawal scale such as the Clinical Institute Withdrawal Assessment (CIWA AD; Sellers et al. 2000) in order to rate the severity of withdrawal and the response to medication. Patients in good physical condition with uncomplicated mild to moderate alcohol withdrawal symptoms usually can be treated as outpatients.

A typical outpatient regimen requires the patient to attend the clinic daily for 5–10 days to receive clinical evaluations, multiple vitamins, and gradually decreasing benzodiazepine pharmacotherapy. A typical medication dosing regimen involves giving enough benzodiazepine on the first day of treatment to relieve withdrawal symptoms. The dose should be adjusted if withdrawal symptoms increase or if the patient complains of excessive sedation. Over the next 5–7 days, the dose of benzodiazepine is tapered to zero. Most clinicians use longer-acting benzodiazepines such as clonazepam, chlordiazepoxide, or diazepam. The usual starting dose of medication on the first day is 25–50 mg of chlordiazepoxide or 10 mg of diazepam given every 6 hours. In an outpatient setting, oxazepam may be particularly useful because it is associated with less abuse and does not require hepatic biotransformation, an important consideration for alcoholics with liver disease.

The diagnosis of delirium tremens is given to patients who have marked confusion and severe agitation in addition to the usual alcohol withdrawal symptoms. It is important to remember that there is a risk of mortality approaching 5% in patients with severe alcohol withdrawal symptoms. Patients who have medically complicated or severe alcohol withdrawal must be treated in a hospital. Benzodiazepines usually will be sufficient to calm agitated patients; however, some patients may require intravenous medication to control extreme agitation.

Relapse Prevention

All patients should be engaged in long-term outpatient care after detoxification. Referral to an AA group is often very useful, but this should not be expected to replace a case manager or therapist. A multipronged approach involving AA, counseling, and medication has the best chance of being successful. Three different kinds of medication have received U.S. Food and Drug Administration (FDA) approval.

Disulfiram

In 1951, disulfiram (Antabuse) became the first medication to be approved by the FDA for the treatment of alcohol dependence other than detoxification. Disulfiram inhibits a key enzyme, aldehyde dehydrogenase, involved in breakdown of ethyl alcohol. After drinking, the alcohol–disulfiram reaction produces excess blood levels of acetaldehyde, which is toxic in that it produces facial flushing, tachycardia, hypotension, nausea and vomiting, and physical discomfort. The usual maintenance dosage of disulfiram is 250 mg/day.

There have been only a few randomized, controlled trials of disulfiram, and these trials have had mixed results for drug efficacy (Peachy and Naranjo 1984). The most comprehensive trial was the Veterans Administration (VA) Cooperative Study of disulfiram treatment of alcoholism. This study was conducted with male veterans and found no differences between disulfiram, 250 mg/day and 1 mg/day (an ineffective dose), and placebo groups in total abstinence, time to first drink, employment, or social stability. Among patients who drank, those in the 250-mg disulfiram group reported significantly fewer drinking days (Fuller et al. 1986).

The main problem with disulfiram is that frequently patients stop taking it and relapse to drinking (Goodwin 1992). Disulfiram is most effective when it is used in a clinical setting that emphasizes abstinence and offers a mechanism to ensure that the medication is taken. Drug compliance may be successfully ensured either by giving the medication at 3- to 4-day intervals in the physician's office or at the treatment center or by having a spouse or family member administer it.

Naltrexone

Naltrexone is a specific opiate receptor antagonist developed for the treatment of heroin addiction. In animal models of alcohol drinking, it was found to reduce the self-administration of alcohol. Beginning in 1983, it was tested as an adjunctive therapy for alcoholism and was found to prevent relapse in some, but not all, patients (Volpicelli et al. 1990, 1992).

After replication of these findings by other researchers (O'Malley et al. 1992), naltrexone was approved by the FDA for use in alcoholism. The first use of naltrexone was to test the hypothesis that at least a part of the reward from alcohol is mediated by the endogenous opioid system. Studies in animal models and in humans have supported that hypothesis (Volpicelli et al. 1995). There have also been reports of reduction in alcohol craving (O'Malley et al. 2002). Alcoholics in treatment get no adverse effects if they drink alcohol while on naltrexone, but they frequently report that it is no longer rewarding. In 2006, the FDA approved an extended-release depot version of naltrexone that is effective with only one injection per month. This is a major treatment advance because the requirement of daily dosing of the oral form led to poor adherence and more relapse. Of course, opioid peptides may not be the only brain system involved in alcohol reinforcement. Norepinephrine, dopamine, serotonin, and γ-aminobutyric acid (GABA) may also be involved in alcohol craving and consumption. Medications aimed at these neurotransmitters are currently in development.

Acamprosate

Another FDA-approved pharmacotherapy for alcohol dependence is acamprosate, whose chemical name is calcium acetyl homotaurinate. Structurally, acamprosate is similar to the amino acid taurine and has been shown to have several actions on the GABA–*N*-methyl-D-aspartate (NMDA) complex. Acamprosate has been reported to be a safe and effective treatment for alcoholism in several controlled studies. In 1985, Lhuintre et al. published the results of a double-blind study in which 85 subjects, described as severely alcoholic, were randomly assigned to 3 months of treatment with either acamprosate or placebo. Seventy subjects completed the trial, and of these, 20 of 33 (61%) acamprosate-treated subjects and 12 of 37 (32%) placebo-treated subjects were abstinent during the study. Positive results were reported for two subsequent placebo-controlled trials (Lhuintre et al. 1990; Paille et al. 1995) in which the total number of abstinent days was higher for acamprosate-treated subjects compared with placebo-treated subjects. In 1996, the reports of two German double-blind, placebo-controlled studies were published. In the first trial, Sass et al. (1996) studied 272 subjects randomly assigned to a year of treatment with either acamprosate or placebo and evaluated for an additional 12 months following the discontinuation of study medication. Compared with placebo-treated subjects, the subjects who received acamprosate had a significantly lower dropout rate, a greater number of days before their first drink, and a greater number of days of total abstinence during the study.

The second study, which had a similar design, involved 455 subjects and was conducted by Whitworth et al. (1996). The results of this trial were that acamprosate was superior to placebo with respect to the number of dropouts, relapse rate, and total days of abstinence. Interestingly, 18% of the acamprosate-treated subjects, compared with 7% of the placebo-treated subjects, remained continuously abstinent a year after discontinuation of study medication. Subsequently, acamprosate was studied in a multiclinic trial in the United States (Mason and Ownby 2000) and in a large National Institutes of Health–sponsored trial comparing acamprosate, naltrexone, and placebo (Anton et al. 2006). Although acamprosate trials in the United States have not been positive, the clear results of the European trials were sufficient to merit FDA approval in 2004.

Alcoholism With Other Coexisting Mental Disorders

Depression commonly occurs in alcoholic individuals. The above anticraving medications can be used in combination with all antidepressants, including monoamine oxidase inhibitors (MAOIs), if they are otherwise indicated. Antidepressants alone have not been found to be consistently useful in reducing drinking, but in depressed persons with alcoholism, they are effective in improving mood and overall well-being.

NICOTINE

According to the 2000 National Household Survey, an estimated 65.5 million Americans, or 29% of the

population, reported current use of tobacco. Most tobacco users, 55.7 million, smoked cigarettes, whereas the remainder smoked cigars and pipes or used smokeless tobacco (Substance Abuse and Mental Health Services Administration 2001). Tobacco accounts for approximately 400,000 deaths per year. Since the mid-1960s, the incidence of smoking in the United States has progressively decreased by about 1% per year (Substance Abuse and Mental Health Services Administration 2001). This remarkable change in tobacco use is a consequence of the realization by society that tobacco-related mortality and morbidity are entirely preventable. Most of these smokers have symptoms that meet the DSM-IV-TR (American Psychiatric Association 2000) criteria for the substance use disorder nicotine dependence. The behavioral aspects of nicotine dependence are similar to those for alcohol and opiate dependence, as well as the production of tolerance and physical dependence. In about 80% of smokers (Gross and Stitzer 1989), nicotine abstinence leads to well-described withdrawal signs and symptoms (Hughes and Hatsukami 1986).

Pharmacotherapy in the form of nicotine replacement has been a key element in reducing withdrawal symptoms and initiating smoking cessation. More recently, nonnicotine medications that can be used in combination with nicotine replacement have become available.

Nicotine Replacement

Nicotine replacement can be obtained over the counter in the form of gum, patch, or nasal spray. Nicotine replacement reduces irritability and withdrawal symptoms such as sleep disturbance, difficulty concentrating, and restlessness. Transdermal nicotine is initially administered in 15- to 21-mg patches for 4–12 weeks, followed by lower-dose patches for up to another 8 weeks. Transdermal nicotine also has excellent documentation for its ability to decrease the severity of withdrawal symptoms and also to decrease craving for tobacco (Daughton et al. 1991; Tonnesen et al. 1991).

Neither gum nor transdermal nicotine has any long-term effect in preventing weight gain after cessation of smoking. Both nicotine preparations provide a significant advantage over placebo in smoking cessation. Stitzer (1991) reviewed seven double-blind, placebo-controlled smoking cessation trials in which nicotine gum was used. Abstinence rates at 4–6 weeks were 73% for nicotine gum compared with 49% for placebo gum. Most of the transdermal nicotine double-blind studies were reviewed by Palmer et al. (1992), who found that quit rates at 4–6 weeks were 39%–71% for transdermal nicotine compared with 13%–41% for the placebo patches. The FDA approved nicotine gum in 1981 and transdermal nicotine in 1991 as prescription medications, and in 1996 both were approved for over-the-counter (nonprescription) use. Beyond the initiation of abstinence, nicotine preparations are associated with a progressive relapse to smoking. After 1 year, abstinence rates are about 25% for the nicotine gum and patch compared with 12% for placebo (Benowitz 1993).

The nasal spray and the inhaler are preparations that provide rapid-release forms of nicotine. The potential advantage of these rapid-release preparations is that they closely simulate smoking by providing a rapid plasma concentration and oral and sensory stimulation. The results from the initial trials for the nasal spray (Schneider et al. 1995; Sutherland et al. 1992) and the inhaler (Tonnesen et al. 1993) are similar to those for the gum and patch.

Nonnicotine Pharmacotherapies

Bupropion, a monocyclic antidepressant that has noradrenergic and dopaminergic effects, was approved by the FDA as a pharmacotherapeutic agent for smoking cessation. Bupropion reduces craving for nicotine, but the mechanism by which this occurs is not well understood. The results from several studies indicate that the bupropion anticraving effect is related to its action on central nervous system dopamine (Covey et al. 2000). In an initial double-blind trial (Ferry et al. 1992) in which 42 men were randomly assigned to 12 weeks of treatment with bupropion 300 mg/day or placebo, the results showed significantly longer continuous abstinence for bupropion-treated subjects at the end of

treatment, as well as 6 and 12 months after treatment. Hurt et al. (1997) conducted a study that clearly established the efficacy of bupropion as pharmacotherapy for nicotine dependence. The trial involved 615 nondepressed subjects (50% female) who were randomized to either bupropion 300 mg/day or placebo for an 8-week medication phase. At 1 year, the smoking cessation rate was 23% for the bupropion group compared with 12% for the placebo group. Jorenby et al. (1999) reported on a multisite smoking study with 893 subjects in which placebo, bupropion, nicotine patch, and bupropion plus nicotine patch were compared for efficacy as pharmacotherapy for nicotine dependence. The 12-month abstinence rates were 15.5% for placebo, 16.4% for nicotine patch, 30.3% for bupropion, and 35.5% for bupropion plus nicotine patch. Bupropion, alone or in combination with the nicotine patch, was superior to the nicotine patch or placebo. Bupropion has also been found to be useful in adolescent smokers, a time of great vulnerability to addiction (Killen et al. 2006).

Varenicline is the newest medication that was approved in 2006 by the FDA as an aid to smoking cessation. It is an $\alpha 4, \beta 2$ nicotinic acetylcholine receptor partial agonist. Laboratory data suggest that this receptor is involved in the reinforcing effects of nicotine through activation of the brain reward system. Varenicline was tested against bupropion and placebo in two identical multisite studies. In one study (Gonzales and Weiss 1998) of 1,025 smokers, those randomized to varenicline had significantly greater abstinence rates (44%) at 12 weeks than placebo- or bupropion-treated patients. Continuous abstinence to 52 weeks was 29.1% for varenicline, 16.1% for bupropion, and 8.4% for placebo. In the second study (Jorenby et al. 2006), the varenicline group also had significantly greater abstinence rates than the placebo or bupropion groups by week 12, and the rates of continuous abstinence to 52 weeks were 23% for varenicline, 14.6% for bupropion, and 10.3% for placebo. Thus, the clinician has three pharmacotherapy options to aid in smoking cessation, along with a behavioral treatment program.

Smoking and Psychiatric Disorders

The incidence of smoking in persons who abuse alcohol, stimulants, and opiates is about 90%; however, compared with the other two groups, alcoholic patients smoke the most cigarettes (Burling and Ziff 1988). Many of those who work with psychiatric patients have observed that cigarette smoking is extremely common among patients with schizophrenia. Research not only supports this observation but also clearly shows the extraordinarily high rate of smoking in schizophrenic inpatients and outpatients. Goff et al. (1992) studied schizophrenic outpatients and found that 74% smoked, compared with a national average of less than 30%. Between 80% and 90% of a group of institutionalized schizophrenic patients were found to smoke (Matherson and O'Shea 1984). There is no known reason for the high rate of nicotine use by schizophrenic patients. Some have speculated that the dopamine-augmenting effect of nicotine may counterbalance a relative dopamine deficiency that exists in schizophrenic patients (Glassman 1993). However, nicotine-induced changes in other neurotransmitters (e.g., serotonin) (Benwell and Balfour 1982) may help to explain why so many schizophrenic patients smoke. Also, there is speculation that nicotine ameliorates the cognitive deficits in schizophrenia (Sacco et al. 2005). Further research is needed to understand nicotine's involvement in the pathophysiology of schizophrenia. It is not unreasonable to expect that future antipsychotics not only will ameliorate psychiatric symptoms but also may decrease nicotine dependence in schizophrenic patients.

Glassman et al. (1988) conducted pioneering research establishing the link between major depression and cigarette smoking. Based on data from the Epidemiologic Catchment Area (ECA) survey (Regier et al. 1984), they found that 76% of persons with a lifetime history of major depression "had ever smoked" compared with 52% of persons without a depression history. Similarly, the incidence of depression was 6.6% in smokers compared with 2.9% in nonsmokers, and smokers with a history of depression had a low rate of cessation. These findings have been replicated by several investigators,

and the association between depression and smoking is well supported. Another observation is that depressive symptoms appear during smoking cessation in persons with a history of depression (Covey et al. 1990). These researchers also found that alcoholism had the highest association with smoking. Smoking rates among persons with anxiety disorders are at least twice those of persons without a psychiatric diagnosis.

It is unclear what role smoking plays in psychopathology of these disorders. There is some information supporting smoking in these populations as a maladaptive coping strategy (Revell et al. 1985). Future research on smoking in these targeted psychiatric populations may indicate the most efficient treatment approaches for patients who suffer from a combination of nicotine dependence and another psychiatric disorder. Ignoring the nicotine addiction in psychiatric patients, however, is no longer considered acceptable practice.

BENZODIAZEPINES AND OTHER SEDATIVES

The benzodiazepines have largely replaced older sedative-hypnotic agents, such as barbiturates and meprobamate, in clinical use. To a great extent, the benzodiazepines are popular because they are safe in overdose situations and because, when first marketed, they were thought to have no (or almost no) abuse potential. Clinical experience and scientific study have since shown that although the benzodiazepines, as a class of drugs, are certainly safer in isolated overdose situations than the older agents, physiological dependence is possible and occurs with long-term use, even at therapeutic doses.

These findings have touched off a controversy that has yet to be settled. Most patients who are, in fact, physiologically dependent on benzodiazepines do not increase the dose of medication above the physician's prescription or in any other way abuse the prescribed medication. However, if the benzodiazepine were to be abruptly discontinued, the patient would, in all probability, experience a withdrawal abstinence syndrome that could be extremely severe (O'Brien 2005). For instance, abrupt discontinuation of high therapeutic doses of alprazolam has frequently been reported to cause seizures. Thus, any patient receiving a benzodiazepine for a significant length of time, that is, longer than 3–6 months, should be slowly tapered off his or her medication; this does not preclude the possibility of reemergence of the patient's anxiety symptoms, which may necessitate continued use of the medication.

The fact that patients become physiologically dependent on therapeutic doses of benzodiazepines has led some people in the field to equate any use of benzodiazepines in any patient for long-term treatment with abuse of the drug. This is undoubtedly an overstatement of the abuse of these agents. Significant abuse of benzodiazepines does, in fact, occur but is usually seen in patients abusing other drugs also, not in patients who are carefully monitored and are stable taking therapeutically indicated benzodiazepines.

In general, patients who abuse only benzodiazepines are rare; benzodiazepine abuse in combination with abuse of other drugs is much more common. Alcoholic patients will not infrequently abuse benzodiazepines if the opportunity presents, and patients who abuse cocaine and opioids are also likely to use benzodiazepines concomitantly. Studies in alcoholic patients admitted for detoxification have shown that the rate of benzodiazepine use among these patients is between 28% and 41%, as determined by urinalysis (Crane et al. 1988; Ogborne and Kapur 1987; Soyka et al. 1989); generally only about one-third of the patients with a positive urine test result for benzodiazepines admitted to using the drugs. A variety of studies from Europe have examined benzodiazepine use in patients who use illicit opioids and have found that up to 90% of patients use benzodiazepines to some extent, although most patients deny that they use benzodiazepines or state that they use them to mitigate insomnia or anxiety or to reduce withdrawal symptoms.

Methadone-maintained patients often use benzodiazepines, but generally on a sporadic basis. Magura

et al. (1987) showed that 40% of patients in four methadone programs in New York had urine test results that were positive for benzodiazepines, whereas studies in England showed rates of benzodiazepine-positive urine test results of 54% (Lipsedge and Cook 1987) and 59% (Beary et al. 1987) in methadone-maintained patients. In patients who use benzodiazepines in conjunction with other drugs, the issues of abuse and physiological dependence take on a much different meaning than in stable patients taking long-term prescribed benzodiazepines. If these patients use or abuse more than one substance, the use or abuse of benzodiazepines can seriously interfere with drug abuse treatment for other substances; for example, the patient may be discharged from his or her methadone maintenance program for having urine test results that are consistently positive for illicit benzodiazepines. These patients require detoxification from benzodiazepines, with either a benzodiazepine or a phenobarbital taper; evaluation for underlying psychiatric disorders such as generalized anxiety or panic disorder; and relapse prevention techniques for benzodiazepine abuse.

COCAINE

Cocaine abuse in the United States reached epidemic status in the early 1980s. Over the next decade, cocaine use initially decreased and then stabilized. In 2000, an estimated 1.2 million Americans age 12 years and older were current cocaine users. The estimated number of current crack users in 2000 was 265,000 (Substance Abuse and Mental Health Services Administration 2001). According to data from the 2000 Drug Abuse Warning Network (DAWN) Report, cocaine was the illicit substance most frequently associated with hospital emergencies (Substance Abuse and Mental Health Services Administration 2001). In 2000, the rate of cocaine mentions was 71 per 100,000 population. This rate has remained essentially the same since 1994.

The selection of potential pharmacotherapies has been based on the current understanding of the neurochemical changes that result from chronic stimulant use (see Chapter 49, "Neurobiology of Substance Abuse and Addiction"). Cocaine administration results in increased levels of dopamine in the region of the nucleus accumbens in rats, which is an important part of the brain reward pathways. Cocaine and other abused substances that increase nucleus accumbens dopamine also *decrease* the threshold for brain stimulation reward (Kornetsky and Porrino 1992) and increase the threshold during cocaine withdrawal after chronic cocaine (Koob et al. 2004). A large number of human imaging and animal model studies demonstrate that chronic cocaine exposure dysregulates dopamine function in reward-related brain regions (Dackis and O'Brien 2003).

Pharmacotherapy for cocaine dependence must be considered separately from pharmacotherapy used to treat complications involved in cocaine abuse such as depression and psychotic reactions. Gawin and Kleber (1986) initially described a three-phase cocaine withdrawal syndrome consisting of crash, withdrawal, and extinction. Although this description of cocaine withdrawal found quick acceptance by many clinicians, it was not observed to be valid in several inpatient trials (Miller et al. 1993; Satel et al. 1991; Weddington et al. 1990). In these trials, only mild abstinence symptoms, including depression, anxiety, fatigue, and impaired concentration, were found; the symptoms declined in a linear fashion over the course of 1–2 weeks (Satel et al. 1991; Weddington et al. 1990). However, despite the fact that cocaine withdrawal is not considered to be medically significant, cocaine withdrawal symptom severity is important because of its predictive value. Kampman et al. (2004b) used an instrument called the Cocaine Selective Severity Assessment to measure cocaine withdrawal symptom severity. They found that cocaine withdrawal symptom severity at the start of treatment predicted outcome in several trials. Severe cocaine withdrawal may result from cocaine-induced neuroadaptations and may identify patients with more persistent hedonic dysregulation (Dackis 2005).

Over the past three decades, many agents have been tested and demonstrated to be ineffective as treatments for cocaine dependence. It is noteworthy that dopamine antagonists actually destabilize cocaine-addicted individuals (Grabowski et al. 2000; Kampman et al. 2003), perhaps by exacerbating

cocaine-induced dopamine dysregulation. Conversely, the dopamine-enhancing agents disulfiram and modafinil promoted abstinence in controlled trials (Carroll et al. 2004; Dackis et al. 2005). Modafinil also blunted cocaine-induced euphoria in three controlled human laboratory studies (Dackis et al. 2003; Myrick et al. 2004; Hart et al. 2006) and is under current investigation in three large clinical trials.

Advances in the neurobiology of cocaine dependence have guided medication development by identifying neuronal mechanisms associated with specific aspects of cocaine dependence, such as euphoria, withdrawal, and cue-induced craving (Dackis 2005). While dopamine-enhancing agents may reverse neuroadaptations that interfere with the attainment of abstinence, GABA-enhancing agents may prevent relapse in abstinent patients by dampening cue-induced craving, which is a persistent clinical phenomenon that leads directly to recidivism. Topirimate, a GABA-enhancing agent, may promote abstinence by dampening cue-induced craving (Kampman et al. 2004a). Similarly, modafinil and vaccines that reduce cocaine's entry into the brain may promote abstinence by blocking cocaine-induced euphoria (Sofuoglu and Kosten 2005).

The lack of success in identifying an effective medication for treating cocaine dependence has not dampened scientific enthusiasm or impeded further research. On the contrary, there is renewed interest in studying various methods of altering the physiological effects of cocaine. One promising type of relapse prevention pharmacotherapy is not a medicine but a vaccine capable of stimulating the production of cocaine-specific antibodies. Several cocaine vaccines are under development. One of these vaccines, called TACD, works by stimulating the production of cocaine-specific antibodies that bind to cocaine molecules and prevent them from crossing the blood–brain barrier. Because cocaine is inhibited from entering the brain, its euphoric and reinforcing effects are reduced. Cocaine itself is too small a molecule to provoke an immune response, so the vaccine attaches a large protein molecule to a cocaine molecule, thus allowing the immune system to recognize cocaine and produce antibodies against it. TACD can stimulate the production of cocaine-specific antibodies in rats and mice, and the vaccine is effective in reducing cocaine self-administration in rodent models (Fox et al. 1996; Kantak et al. 2000). TACD was administered to 34 former cocaine users in a Phase I trial. The vaccine was well tolerated, and dose-related levels of anticocaine antibodies were detected (Kosten et al. 2002; Martell et al. 2005).

METHAMPHETAMINE

In recent years, methamphetamine abuse has become a severe problem, especially in Hawaii and western continental United States. Methamphetamine is a stimulant that possesses stronger dopamine augmentation than cocaine and for a longer duration. While cocaine temporarily blocks dopamine reuptake at synapses, amphetamines also reverse the transporter, thus releasing even more of the neurotransmitter into synapses. Amphetamine, dextroamphetamine, methamphetamine, phenmetrazine, methylphenidate, and diethylpropion all produce behavioral activation similar to that of cocaine. Intravenous or smoked methamphetamine produces an abuse/dependence syndrome similar to that of cocaine, but paranoid psychosis appears to be more common with amphetamine abuse. A different picture arises when oral stimulants are prescribed in a weight reduction program. These drugs do reduce appetite, with accompanying weight loss, on a short-term basis, but the effects diminish over time as tolerance develops. In rodents, there is a rebound of appetite and weight gain when amphetamine use is stopped. In obese humans, weight loss after amphetamine treatment is usually temporary. Anorectic medications, therefore, are not considered to be a treatment for obesity by themselves but rather a short-term adjunct to behavioral treatment programs. Drug abuse manifested by drug-seeking behavior occurs in only a small proportion of patients given stimulants to facilitate weight reduction.

No medication has yet achieved FDA approval for the treatment of methamphetamine addiction, but several that have received positive reports in cocaine addiction treatment such as modafinil are

currently in clinical trials for methamphetamine (Ling et al. 2006).

OPIOIDS

Pharmacotherapy for opioid dependence has a long history, in part because "heroinism" was one of the first recognized drug problems in the United States and because therapeutically used congeners of the drug of abuse, heroin, were readily available. Later studies have shown only limited success with nonpharmacological treatment.

Detoxification From Opioid Dependence

The classical method of opioid detoxification was, and remains, short-term substitution therapy. The medication traditionally used has been methadone, at a sufficient dose to suppress signs and symptoms of heroin withdrawal; the methadone is then tapered over a period ranging from 1 week to 6 months. The idea behind a rapid (i.e., 1- to 2-week) detoxification regimen is to achieve total opioid abstinence quickly so that treatment can be continued in a drug-free setting. Detoxification usually can be accomplished in 4–7 days in an inpatient setting, whereas more time is often required in the outpatient setting to minimize patient discomfort. Most practitioners consider 21 days sufficient for short-term outpatient detoxification. However, many patients have very chaotic lives when presenting for treatment and require a period of stabilization before they can hope to maintain a drug-free lifestyle. There is no evidence that more rapid detoxification leads to better long-term outcomes. As discussed below, the regulations for opioid treatment facilities require that patients be dependent on opioids for at least 1 year before they may be admitted to methadone maintenance. The 6-month stabilization/detoxification regimen allows these patients to work on the most acute personal and employment problems while they are stabilized at a relatively low dosage (30–40 mg/day) of methadone and then are detoxified from methadone to continue treatment in a drug-free setting. Unfortunately, the relapse rate after detoxification and drug-free counseling is very high, and long-term maintenance on medication is usually necessary.

The partial opiate agonist buprenorphine received FDA approval in 2002 for the treatment of opioid withdrawal and for maintenance. A major change in the U.S. approach to addiction treatment occurred with passage of a law in 2000 that allows physicians who have a special federal certification to prescribe buprenorphine in their office rather than limiting access, as is the case with methadone.

Buprenorphine has been studied for efficacy in suppressing withdrawal signs and symptoms. In outpatient trials, Bickel et al. (1988) showed that buprenorphine was as effective as methadone in a 10-week double-blind trial (4 weeks on medication taper followed by 6 weeks of placebo). In an open trial, Kosten and Kleber (1988) compared three doses of buprenorphine and found that 4 mg, administered sublingually, was superior to 2 or 8 mg in suppressing signs and symptoms of withdrawal, although illicit opiates were present in the urine of approximately equal numbers of patients in both the 2-mg and the 4-mg dose groups.

There has always been concern about substitution detoxification on the basis that the physician is prolonging the problem by prescribing an addictive medication, even with a tapering regimen. Many of the symptoms of opioid withdrawal (e.g., diaphoresis, hyperactivity, and irritability) appear to be mediated by overactivity in the sympathetic nervous system. This led Gold et al. (1978, 1980) to attempt to depress this overactivity and thereby ameliorate the withdrawal abstinence syndrome by using adrenergic agents that have no abuse potential. Clonidine, an α-adrenergic agonist with inhibitory action primarily at an autoreceptor in the locus coeruleus, was effective in inpatient populations in decreasing the signs and symptoms of opioid withdrawal. Outpatient detoxification with clonidine has not been as successful as inpatient treatment. Inpatient studies reported an 80%–90% success rate, whereas outpatient studies reported success rates as low as 31% in detoxifying patients from methadone and 36% in detoxifying patients from heroin. The problems identified in outpatient clonidine detoxification include 1) access to heroin and other opioids, 2) lethargy, 3) insomnia, 4)

dizziness, and 5) oversedation. The last four adverse effects were noted in inpatient populations during detoxification with clonidine but were easily managed in the hospital setting.

Because the side effects of clonidine were unacceptable to many patients, other α-adrenergic agonists have been investigated for use in detoxifying opioid-dependent patients. Lofexidine is widely used for this purpose in the United Kingdom and is in clinical trials in the United States (Gerra et al. 2001).

Ultrarapid detoxification under general anesthesia has been used in some settings with claims of a painless and rapid method to attain the opiate-free state. A randomized comparison of this procedure with a standard buprenorphine detoxification was conducted, and the results showed no advantage for the ultrarapid procedure (Collins et al. 2005). The major hurdle for the treatment of opiate addiction is prevention of relapse, and the method or duration of the detoxification makes no difference.

Maintenance Treatment of Opioid Dependence

Methadone maintenance has been the mainstay of the pharmacotherapy for opioid dependence since its introduction by Dole and Nyswander (1965). Since the 1970s, levo-α-acetylmethadol (LAAM), a long-acting congener of methadone, has been used experimentally for maintenance treatment. It was approved by the FDA for this purpose in 1993 but was later withdrawn from the U.S. market by the pharmaceutical company because of concerns about possible cardiac arrhythmias. With the availability of buprenorphine in 2002, there are again two options for agonist maintenance treatment: methadone and buprenorphine.

Methadone

As discussed earlier in this chapter, methadone has been used for both short- and long-term detoxification from opioids. Methadone maintenance, however, is designed to support patients with opioid dependence for months or years while the patient engages in counseling and other therapy to change his or her lifestyle. Experience with methadone encompassing approximately 1.5 million person-years strongly showed methadone to be safe and effective (Gerstein 1992). Furthermore, this experience has shown that although patients on methadone maintenance show physiological signs of opioid tolerance, there are minimal side effects, and patients' general health and nutritional status improve.

This approach to the treatment of opioid dependence has been controversial since its beginning. Physicians and other treatment professionals who consider addiction to be a brain disease have little or no problem treating patients with an active drug for long periods of time, especially in light of repeated treatment failures in the absence of active medication therapy. However, many people view methadone maintenance as simply substituting a legal drug for an illegal one and refuse to accept any outcome other than total abstinence from all drugs. These people point to long-term follow-up studies of methadone maintenance patients (see Maddux and Desmond 1992) that show that only 10%–20% of the patients are completely abstinent (defined as not being enrolled in methadone maintenance and not using illicit opioids) 5 years after discharge from the maintenance program. However, long-term follow-up studies of patients discharged from drug-free treatment programs show that only 10%–19% of opioid-dependent patients are abstinent at 3- or 5-year time points (see Maddux and Desmond 1992) when the same definition is used. The DSM course specifier "on agonist therapy" applies to those patients who do well on methadone or buprenorphine while continuing the medication and do not use illegal drugs.

Outcome studies conducted with patients in maintenance treatment consistently show that these patients have marked improvement in various measures. Investigators have shown up to an 85% decrease in criminal behavior, measured by self-report or arrest records. Employment among maintenance patients ranges from 40% to 80%. Gerstein (1992) quoted a Swedish study published in

1984 showing the results over 5 years in 34 patients who applied for treatment to the only methadone clinic in Sweden at the time. The 34 patients were randomly assigned to either methadone maintenance or outpatient drug-free therapy; the patients in drug-free treatment could not apply for methadone for a minimum of 24 months after being accepted into the study. After 2 years, 71% of the methadone patients were doing well, compared with 6% of the patients admitted to drug-free treatment. After 5 years, 13 of 17 (76%) patients remained on methadone and were free of illicit drugs, whereas 4 of 17 (24%) patients had been discharged from treatment for continued drug use. Of the 17 drug-free treatment patients, 9 (53%) had subsequently been switched to methadone treatment, were free of illicit drug use, and were "socially productive." Of the remaining 8 patients, 5 (63%) were dead (allegedly from overdose), 2 (25%) were in prison, and 1 (13%) was drug free.

Furthermore, although previous generations of drug abusers had hepatitis B, endocarditis, and other infections, in this age when injection drug use and concomitant sharing of needles and syringes place a patient at risk for HIV infection, the medical consequences of heroin dependence must be taken into account when determining appropriate therapy for a patient. These issues are currently being studied by a variety of methods, but the overall clinical impression of increased general health in methadone maintenance patients is very strong. Additionally, Metzger et al. (1993) undertook a study of HIV seroconversion rates in opioid-dependent subjects. In this study, 152 subjects were in methadone maintenance treatment and 103 subjects were out of treatment. At baseline, 12% of the subjects were HIV positive (10% of in-treatment and 16% of out-of-treatment subjects); follow-up of HIV-negative subjects over 18 months showed conversion rates of 3.5% for in-treatment subjects and 22% for those remaining out of treatment. These data suggest that although transmission of HIV still occurs, opioid-abusing injection drug users in methadone maintenance programs have a significantly lower likelihood of becoming infected than do patients who are not in treatment.

Methadone maintenance programs in the United States are accredited by agencies such as Joint Commission on Accreditation of Healthcare Organizations, approved under regulations by the Center for Substance Abuse Treatment (CSAT) in the Substance Abuse and Mental Health Services Administration (SAMHSA) of the Department of Health and Human Services and the Drug Enforcement Agency (DEA). A program must be accredited and its physicians licensed for a methadone maintenance program in order to prescribe or dispense more than a 2-week supply of any opioid to a patient known or suspected to be dependent on opioids. Most clinics treat ambulatory outpatients and are open 6–7 days per week, requiring patients to come into the clinic daily to receive medication unless and until a patient has "earned" privileges (take-home medication) by compliance with the clinic rules and abstinence from illicit substances. For a person to be eligible for methadone maintenance, he or she must be at least 18 years old (or have consent of the legal guardian) and must be physiologically dependent on heroin or other opioids for at least 1 year. The treatment regulations define a 1-year history of addiction to mean that the patient was addicted to an opioid narcotic at some time at least 1 year before admission and was addicted, either continuously or episodically, for most of the year immediately before admission to the methadone maintenance program. A physician must document evidence of current physiological dependence on opioids before a patient can be admitted to the program; such evidence may be a precipitated abstinence syndrome in response to a naloxone challenge or, more commonly, signs and symptoms of opioid withdrawal, evidence of intravenous injections, or evidence of medical complications of intravenous injections. Exceptions to these requirements are patients who have recently been in penal or chronic care, previously treated patients, or pregnant patients; in these cases, patients need not show evidence of current physiological dependence, but the physician must justify their enrollment in methadone maintenance. A person younger than 18 years must have documented evidence of at least two attempts at short-term detoxification or drug-free treatment (the episodes must be separated by at least 1 week) and have the consent of his or her parent or legal guardian.

Dosage of methadone is an important variable and should be adjusted according to the level of

physical dependence. A careful study of performance of methadone programs showed continued heroin use among low-dose patients. Among patients receiving at least 71 mg/day of methadone, no heroin use was detected, whereas patients receiving 46 mg/day of methadone or lower were five times more likely to use heroin than those receiving higher doses (Ball and Ross 1991). Furthermore, McLellan et al. (1993) showed, in a comparison of three levels of treatment services in which all patients received at least 60 mg/day of methadone, that "enhanced methadone services" patients (methadone plus counseling and on-site medical/psychiatric, employment, and family therapy) had fewer positive urine test results for illicit substances than did patients in the "standard services" (methadone plus counseling) group or the "minimum services" (methadone alone) group. The standard services group did significantly better in treatment than did the minimum services group, and in fact, 69% of the minimum services group required transfer to a standard program 12 weeks into the study because of unremitting use of opioids or other illicit drugs.

Yet another issue that has engendered a great deal of controversy is the treatment of opioid dependence in pregnant women. Those who are philosophically opposed to methadone treatment would advocate that any woman using illicit opioids (heroin) or enrolled in methadone maintenance who became pregnant should be detoxified. It is currently estimated that up to 3% of infants born each year have had intrauterine exposure to opioids. Because many women with substance abuse problems fear all organizations, including medical ones, they frequently have little or no prenatal care, exposing themselves and their babies to the complications of unsupervised pregnancy in addition to the severe stressor of maternal addiction. The complications and treatment of maternal opioid addiction and the effects on the fetus and neonate have been discussed by Finnegan (1991) and Finnegan and Kandall (1992). For the purposes of this chapter, it should be noted that current evidence shows that pregnant women who wish to be detoxified from opioids (either heroin or methadone) should not be detoxified before gestational week 14 because of the potential risk of inducing abortion or after gestational week 32 because of possible withdrawal-induced fetal stress (see Finnegan 1991). Most clinicians dealing with pregnant opioid-dependent patients advocate methadone maintenance at a dose of methadone that maintains homeostasis and eliminates opioid craving; this dose must be individualized for each patient and managed in concert with the obstetrician.

Buprenorphine

Buprenorphine is a partial agonist of μ opioid–type receptor and is a clinically effective analgesic agent with an estimated potency of 25–40 times that of morphine (Cowan et al. 1977). Buprenorphine was approved by the FDA for the treatment of opiate addiction in 2002 in addition to its use as an analgesic agent. Human pharmacology studies have shown buprenorphine to be 25–30 times as potent as morphine in producing pupillary constriction, but buprenorphine was less effective in producing morphinelike subjective effects (Jasinski et al. 1978). Furthermore, these studies showed that the physiological and subjective effects of morphine (15–120 mg) were significantly attenuated when morphine was administered 3 hours after buprenorphine in patients maintained on 8 mg/day of buprenorphine; the physiological and subjective effects of 30 mg of morphine also were tested at 29.5 hours after the last dose of chronically administered buprenorphine and were again significantly attenuated.

Studies in opiate-abusing patients have shown that buprenorphine can be administered sublingually rather than subcutaneously, the route most commonly used for analgesic effect, with only a moderate decrease in potency, 1.0 mg subcutaneously being equal to 1.5 mg sublingually (Jasinski et al. 1989). Early clinical trials with opioid-dependent patients found that patients would tolerate the sublingual route, that the dose of buprenorphine could be rapidly escalated to effective doses without significant side effects or toxicity (Johnson et al. 1989), and that detoxification from heroin dependence using buprenorphine was as effective as using methadone (Bickel et al. 1988) or clonidine (Kosten and

Kleber 1988). Johnson et al. (1992) compared buprenorphine (8 mg/day sublingually) and methadone (20 mg/day or 60 mg/day) in a 25-week maintenance study and found that buprenorphine was as effective as 60 mg/day of methadone in reducing illicit opioid use and keeping patients in treatment. Both buprenorphine and methadone 60 mg/day were superior to methadone 20 mg/day in this study. A multicenter study compared sublingual doses of 1 mg of buprenorphine with 8 mg of buprenorphine in more than 700 patients. The 8-mg dose was significantly better than the 1-mg dose on outcome measures of opiate-free urine tests and retention in treatment (Ling et al. 1998).

Results from a review of the controlled studies suggest that buprenorphine is as effective as moderate dosages of methadone (e.g., 60 mg/day), although it is not clear whether it can be as effective as higher methadone dosages (80–100 mg/day) in patients requiring higher dosages for maintenance therapy. A Swedish randomized trial of buprenorphine/naloxone combination versus standard methadone treatment reported equal results as measured by opiate-free urines and improvement on the Addiction Severity Index (Kakko et al. 2007).

Both detoxification and maintenance studies have shown that the abrupt discontinuation of buprenorphine in a blind fashion causes only very minor elevations in withdrawal scores on any withdrawal scale (Bickel et al. 1988; Fudala et al. 1990; Jasinski et al. 1978; Johnson et al. 1989; Kosten and Kleber 1988). Because the issue of take-home medication is likely to arise in any opiate maintenance program and because methadone take-home medication has the potential for being diverted to illegal channels, the option of every-other-day buprenorphine dosing has been explored. After 19 heroin-dependent patients were stabilized on buprenorphine, 8 mg/day, for 2 weeks, 9 patients continued to receive buprenorphine daily while the other 10 patients, in a blind fashion, received alternate-day buprenorphine doses, 8 mg/dose, for 4 weeks. Patients reported some dysphoria on days on which they received placebos, and it was also noted that pupils were less constricted on placebo days in the patients on alternate-day therapy, but patients tolerated the 48-hour dosing interval without significant signs or symptoms of opiate withdrawal abstinence (Fudala et al. 1990). This leaves open the possibility of alternate-day medication in the treatment setting, eliminating the need for take-home medication.

Buprenorphine is currently marketed in 4:1 combinations with naloxone (buprenorphine/naloxone sublingual tablets of 2 mg/0.5 mg and 8 mg/2 mg). The goal is to reduce abuse of prescribed buprenorphine by injection instead of sublingual dosage. Mendelson et al. (1999) showed that buprenorphine-to-naloxone combination ratios of 2:1 and 4:1 might be useful in treating opiate dependence by causing significant opiate withdrawal symptoms when the combination is taken intravenously. A multicenter clinical trial compared the efficacy of a sublingual tablet of buprenorphine/naloxone, in a 4:1 ratio, with that of placebo and a buprenorphine mono sublingual tablet. The results showed that both the buprenorphine/naloxone combination and the buprenorphine mono tablets were significantly more effective than placebo in reducing illicit opioid use, reducing opioid craving, and improving global functioning. No difference was noted between the efficacy of the combination and the mono products, and the combination product was as acceptable to the subjects as was the mono product (Fudala et al. 1999). Because the buprenorphine/naloxone combination is now widely prescribed throughout the United States, a monitoring program has been in place since 2002 to detect signs of street use of the medication. Thus far, nonprescribed use is minimal, and careful interviews have found that it is most often used to self-treat withdrawal symptoms but not to get high (C. R. Schuster, C. E. Johanson, T. Cicero, C. O'Brien, S. Schnoll, J. Anthony, C. Boyd, R. Schottenfeld, and M. Ensminger, "Surveillance Report—Subutex/Suboxone (July 1–September 30, 2007)," personal communication, December 24, 2007).

Drug Addiction Treatment Act of 2000

The Drug Addiction Treatment Act of 2000 (DATA) allows for the use of opioid medications in the office-based treatment of opioid dependence, provided that both the medication and the physician

meet the criteria set forth by the act. The medication must be approved by the FDA for the treatment of opioid dependence and be scheduled in C-III, C-IV, or C-V; medications in Schedule C-II, such as methadone, are not included in the act. The physician must be a "qualified" physician and have an addendum to his or her DEA license to prescribe medications under DATA 2000. Qualifying physicians under this law, however, will be able to more effectively treat opioid dependence in their offices, without referring patients to opioid treatment clinics. The only medications currently available that meet the requirements of DATA are buprenorphine and buprenorphine/naloxone combinations.

Relapse Prevention

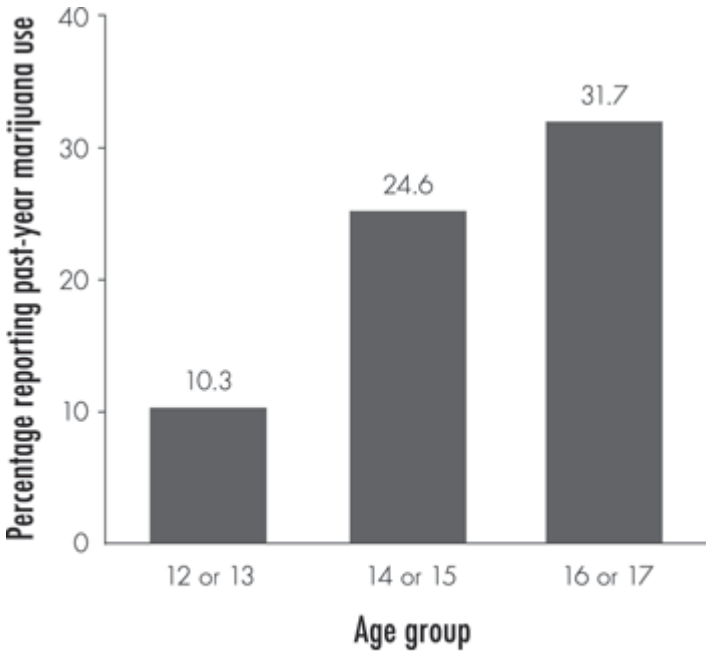
As has been noted earlier in this chapter, various methods of detoxifying patients from opioids have been developed, from substitution and rapidly tapering the dose of opioid to long-term methadone maintenance and a very gradual methadone taper. These methodologies are, by and large, unsuccessful in achieving permanent opioid abstinence in patients. It has long been thought that both conditioned reactivity to drug-associated cues (O'Brien et al. 1977; Wikler 1973) and protracted withdrawal symptoms (Martin and Jasinski 1969) contribute to the high rate of opioid relapse. The use of a blocking dose of a pure opioid antagonist would allow the patient to extinguish the conditioned responses to opioids by blocking the positive reinforcing effects of the illicit drugs. Naltrexone was shown to be orally effective in blocking the subjective effects of morphine for up to 24 hours (Martin et al. 1973). Patients using naltrexone maintenance for relapse prevention need to be carefully screened because they must be opioid free at the start of naltrexone administration. Many practitioners administer a naloxone challenge, which must be negative, before starting naltrexone. Naltrexone is usually administered either daily (50 mg) or three times weekly (100 mg, 100 mg, and 150 mg). Although naltrexone is pharmacologically able to block the reinforcing effects of opioids, the patient must take the medication in order for it to be effective. Many opioid-addicted patients have very little motivation to remain abstinent. Fram et al. (1989) reported that of 300 inner-city patients offered naltrexone, only 15 (5%) agreed to take the medication, and 2 months later, only 3 patients were still taking naltrexone. However, patients with better-identified motivation, among them groups of recovering professionals (e.g., physicians, attorneys) and federal probationers who face loss of license to practice a profession or legal consequences, have significantly better success with naltrexone.

A group of federal probationers with a history of opiate addiction were randomly assigned to either naltrexone or treatment as usual. The group receiving naltrexone had significantly fewer opiate-positive urines, and most importantly, the reincarceration rate of the naltrexone group was half that of the control group at 6 months. In 2006, a depot formulation was approved by the FDA for the treatment of alcoholism (Garbutt et al. 2005). Approval for opiate addiction was not requested, but laboratory studies showed the medication to be effective for 30–40 days in blocking usual doses of injected opiates (Bigelow et al. 2006). A clinical trial of another formulation of depot naltrexone, not yet FDA approved, was found to be effective in a placebo-controlled clinical trial (Comer et al. 2006). Thus, the marketed depot version of naltrexone is yet another option for long-term relapse prevention in patients detoxified from opiate addiction.

HALLUCINOGENS

The use and abuse of hallucinogens wax and wane much more than the use of some other drugs, such as alcohol and opioids. The major drugs of abuse that fall into this classification are cannabis and related compounds, lysergic acid diethylamide (LSD) and other indolealkylamines (psilocybin), phencyclidine (PCP) and its congeners, and hallucinogenic amphetamine congeners such as methylenedioxymethamphetamine (MDMA, "ecstasy"). Cannabis has a relatively constant rate of use, but its use alone usually does not cause the user to seek medical attention. That has changed somewhat in recent years, as will be described below. LSD (and related compounds) use has changed from the pattern set in the 1960s, when users lived together communally and the lifestyle of the group

frequently revolved around the psychedelic experience. Today, LSD use occurs in isolated groups, polysubstance abusers, and adolescents and young adults who frequent "rave" clubs. Most users of LSD and related compounds are not seen in emergency departments, but occasionally patients experiencing acute adverse reactions to these drugs are brought to medical attention. The most frequent adverse effects of LSD and related compounds are acute panic reactions. Most acute panic reactions, the "bad trips," do not require any intervention other than a calm atmosphere and reassurance, but occasionally a patient will be seen who benefits from a low dose of a benzodiazepine to decrease the anxiety associated with the experience. Likewise, intoxication with MDMA rarely requires more than reassurance or, occasionally, acute benzodiazepine administration, again to enable the patient to deal with the anxiety associated with an adverse experience. However, more recently, as MDMA use has become more popular, particularly in dance or "rave" club situations, more serious effects have been noted. These effects include things such as grinding of the teeth, causing dental problems, as well as more significant medical complications, most notably severe dehydration. It is not known whether the combination of alcohol and MDMA increases the risk of dehydration, but the combination is a frequent occurrence.



PCP intoxication, however, can have serious psychiatric and medical complications. An acute psychotic state can be produced by very low doses of PCP, but behavioral disinhibition, frequently accompanied by anxiety, rage, aggression, and panic rather than by the core psychotic effects, necessitates treatment in most cases in which treatment is mandated. There is no convincing evidence of the superiority of either benzodiazepines or neuroleptics in treating the acute reaction to PCP. Benzodiazepines are frequently used because they have a rapid onset of action and because they can be titrated intravenously. If a neuroleptic is to be used, haloperidol is the most commonly used agent because many other neuroleptics have significant interaction with the anticholinergic properties of PCP itself. There is a paucity of information on chronic use of PCP and on treatment, if indicated, of the chronic user.

MARIJUANA

Marijuana is mentioned as an hallucinogen, but its use is so common that it deserves special consideration. The cannabis plant has been cultivated for centuries both for the production of hemp fiber and for its presumed medicinal and psychoactive properties. The smoke from burning cannabis contains many chemicals, including 61 different cannabinoids that have been identified. One of these, delta-9-tetrahydrocannabinol (Δ-9-THC), produces almost all of the characteristic pharmacological effects of smoked marijuana (Iversen 2000). The pharmacological effects of Δ-9-THC vary according to the dose, route of administration, experience of the user, vulnerability to psychoactive effects, and setting of use. Intoxication with marijuana produces changes in mood, perception, and motivation, but the effect sought after by most users is the "high" and "mellowing out." This is described as different from the stimulant high and the opiate high. The effects vary with dose, but the typical marijuana smoker experiences a high that lasts about 2 hours. Some users progress to daily use, which is associated with true dependence (addiction) as well as low motivation and possibly increased risk for schizophrenia (Ferdinand et al. 2005).

Rates of marijuana consumption in adults 18 years and older held relatively steady at 4% of respondents in 2002. However, rates of marijuana-related disorders—discrete conditions defined according to criteria established by the American Psychiatric Association—increased from 1.2% to 1.5% of respondents, or from 30.2% overall to 35.6% among marijuana smokers (Compton et al. 2007). In 2007, the National Survey Results on Drug Use estimated that 31.7% of twelfth grade students used marijuana during 2007 (Figure 58–1).

FIGURE 58–1. Percentages of youths ages 12–17 years reporting past-year marijuana use, by age group: 2000.

Source. Reprinted from Substance Abuse and Mental Health Services Administration: 2000 National Household Survey on Drug Abuse Report: Marijuana Use Among Youth. Substance Abuse and Mental Health Services Administration, July 2002. Used with permission.

Marijuana is one of the four major substances of abuse; the others are alcohol, cocaine, and heroin. According to the 2000 DAWN report, marijuana had one of the highest emergency department drug mentions, at 39 per 100,000. From 1994 to 2000, marijuana mentions increased from 17 to 39, or by 141% (Substance Abuse and Mental Health Services Administration 2002). After alcohol use disorders, marijuana abuse had the second highest rate of treatment, with 700,000 persons (Substance Abuse and Mental Health Services Administration 2001).

The usual treatment interventions for marijuana abuse include drug monitoring, individual and group psychotherapy, and education (Hubbard et al. 1999). No pharmacotherapy is available for marijuana abuse. This may soon change, given the recent remarkable discoveries concerning cannabinoids.

There has been an explosive growth of marijuana research. Key to this have been the discoveries of cannabinoid receptors and endocannabinoids (naturally occurring cannabis substances) in humans. The neurobehavioral and genetic aspects of cannabinoids are the focus of numerous ongoing studies (see review by Onaivi 2006). The recent scientific discoveries are significant first steps in understanding the mechanisms by which cannabinoids cause physiological effects.

Marijuana has been proposed for several medical indications, including nausea associated with cancer chemotherapy, glaucoma, and wasting disorders. Also, the discovery of cannabinoid receptors opens the opportunity for the development of specific agonists and antagonists at these receptors that may have important medical value.

SELF-HELP GROUPS

Self-help groups—such as Alcoholics Anonymous, Narcotics Anonymous, and Cocaine Anonymous—that are based on a 12-Step method of recovery can be a valuable source of support for the recovering patient. These groups are a fellowship of recovering people interested in helping themselves and others lead drug-free lives. The groups are very good for reminding people of the adverse consequences of relapse and of the benefits of abstinence. Many recovering people feel that it

is easier and more relevant to hear about some aspects of recovery from another recovering person. Patients can attend meetings as frequently as necessary and can learn more effective management of leisure time. A sponsor, a person in the group with a prolonged time in a drug-free lifestyle, can provide a good role model for a person in recovery, in addition to providing support and encouragement. Self-help groups are also available to non-drug-abusing family members to help them understand the addictive process and how family member dynamics can affect the drug-abusing or recovering family member.

CONCLUSION

Addictive disorders can be caused by a variety of drugs that activate the reward system. The common clinical feature of all addictions is loss of control over drug use so that recurrent compulsive drug taking occurs. Treatment, as with other chronic disorders, is generally effective for at least the short term, but relapses are always possible and even likely. Randomized, controlled clinical trials have demonstrated that the combination of antiaddiction medications and psychotherapy provides the best treatment for addictive disorders.

Chapter 59. Treatment of Eating Disorders

TREATMENT OF EATING DISORDERS: INTRODUCTION

Eating disorders are seen frequently in the clinic, reflecting a combined prevalence in women for anorexia nervosa (AN), bulimia nervosa (BN), and binge-eating disorder (BED) of about 3.5% for the full disorder and 6% if subthreshold disorders are included (Hudson et al. 2007). Males are affected less frequently; about 10% of all cases of AN and BN are in males, with the proportion rising to about 30% for BED in clinical samples. Because much comorbid psychopathology is associated with each of these disorders, including current major depression in about 25% of cases, the treatment plan must take any such disorders into account. Two forms of treatment, psychopharmacological and psychotherapeutic, are effective in the treatment of BN and BED, and possibly in AN. Hence, determining how to sequence or combine treatment modalities is an important issue.

HISTORICAL BACKGROUND

Case histories of starvation, binge eating, and purging have been documented, mostly as rare curiosities, for centuries. The histories of saintly women in the thirteenth to fifteenth centuries who had all the symptoms of AN, including self-induced vomiting, are particularly well documented both in their own writings and in the accounts of others. For these women, starvation was in the service of their religious beliefs (Bynum 1987). Cases of BN were rarely seen in the clinic until their relatively sudden increase throughout the Western world in the late 1970s (Garner et al. 1985). This apparent increase in the prevalence of BN has been attributed to increasing societal pressures on women to maintain a thin body shape. Hence, the motivation for excessive dieting may vary according to the cultural pressures of the times.

Research into the psychopathology and treatment of the eating disorders was relatively slow to develop as compared with such research in depression and the anxiety disorders. This was probably because of the low prevalence of AN and the relatively recent increase in the number of cases of BN. Moreover, BED was only recently recognized as a syndrome, although there is now a large body of literature on the condition. Despite this slow start, sufficient controlled treatment trials are now available to provide guidance to the clinician. This is particularly true for BN, for which psychopharmacological and psychotherapeutic studies began at the same time. Because of the similarity between BN and BED, treatments successful for BN were then applied to BED with some success.

BULIMIA NERVOSA

BN has its onset in late adolescence or early adult life, with a prodromal period characterized by dissatisfaction with body shape and a fear of becoming overweight, followed by dietary restriction and weight loss. Sooner or later, periods of dietary restriction are followed by episodes of binge eating experienced as a loss of control over dietary intake. This, in turn, further aggravates dissatisfaction with body shape and fears of weight gain. Ultimately, the bulimic patient discovers purging, usually in the form of self-induced vomiting, with or without laxative or diuretic use, excessive exercise, or (less commonly) fasting; and in rare cases in the form of chewing food and spitting it out.

DSM-IV-TR (American Psychiatric Association 2000) distinguishes two forms of BN: purging and nonpurging types, the latter characterized by the use of exercise or fasting rather than other compensatory behaviors. The implications of this classification for treatment are unknown. Medical complications of BN are relatively rare; the most serious are potassium depletion and dental caries. Other complications include salivary gland enlargement and exercise injuries. Comorbid psychopathology includes major depression; anxiety disorders, including obsessive-compulsive disorder, social phobia, and panic disorder; alcoholism; and personality disorders, particularly those in the Cluster B spectrum.

Assessment

Assessment should begin with a history of the development of disordered eating, including the psychosocial factors involved in its development. Areas that should be explored include binge eating, purging methods, exercise, and concerns about weight and shape. Eating binges comprise two features: a feeling of loss of control over eating and the eating of a large amount of food. Loss of control appears to be facilitated by the experience of negative affect often deriving from faulty interpersonal interactions (Agras and Apple 2007; Agras and Telch 1998). An objective binge involves eating an amount of food equivalent to an intake of two or more meals. Such binges are required to meet criteria for the diagnosis. Subjective binges consist of a feeling of loss of control but eating less than the required amount for an objective binge. These binges are often quite small and may involve eating a "forbidden" food. The most

common method of purging is self-initiated vomiting. It is important to inquire about the use of ipecac to facilitate vomiting because of its toxic cardiovascular effects. The next most frequent method of purging is the use of laxatives. Diuretics also may be used, but less frequently than laxatives. Chewing food and spitting it out and the use of enemas as purgative methods are occasionally seen. Exercise is also used frequently in an attempt to control weight and shape. It is important to distinguish such exercise from normal exercise patterns. The most common distinguishing feature is an exercise regimen that results in exhaustion or that is compulsively adhered to and that would cause anxiety if it were omitted from the daily routine.

In addition to the history, an electrolyte panel is needed, particularly to check potassium levels, which are low and require correcting in about 5% of individuals with BN. A hematocrit is also useful because anemia may be present. Serum amylase levels also may be elevated. If the patient is not receiving regular dental care, then a referral for such care should be considered because of the erosion of dental enamel and periodontal disease that frequently accompany bulimia. Finally, the assessment should document both past and present comorbid psychiatric disorders because these conditions may have to be taken into account in planning treatment. For example, current major depression may interfere with the patient's ability to adhere to treatment and should be treated together with the eating disorder.

Pharmacological Treatment

Antidepressants

The use of antidepressants in the treatment of BN was sparked by the observation that depression is often a comorbid feature of the disorder (Pope and Hudson 1982). In 1982, two groups of researchers conducted small-scale uncontrolled studies indicating that both tricyclic antidepressants and monoamine oxidase inhibitors reduced binge eating and purging (Pope and Hudson 1982; Walsh et al. 1982). These observations were followed by a series of double-blind, placebo-controlled studies confirming the utility of antidepressants in treating BN, at least in the short term.

A wide range of antidepressant drugs have been found effective, including imipramine (Agras et al. 1987; Mitchell et al. 1990; Pope et al. 1983), desipramine (Agras et al. 1991; Barlow et al. 1988; Blouin et al. 1989; Hughes et al. 1986), phenelzine (Walsh et al. 1988), brofaromine (Kennedy et al. 1993), trazodone (Pope et al. 1989), fluoxetine (Fluoxetine Bulimia Nervosa Collaborative Study Group 1992), fluvoxamine (Milano et al. 2005), and citalopram (Leombruni et al. 2006). Fluoxetine is the only medication approved by the U.S. Food and Drug Administration for the treatment of BN. In these studies, the median rate of decrease in binge eating and purging was 69%, the median recovery rate was 32%, and the mean dropout rate was 23%. In one study involving 77 BN patients (Walsh et al. 2006b) that examined the rate of decline in bulimic symptoms with desipramine, the authors found that those unlikely to respond to the antidepressant could be reliably identified after 2 weeks of treatment.

Antidepressants are prescribed for BN at the same dosages used for treating depression, with the exception of fluoxetine, for which a dosage of 60 mg/day was found to be more effective than 20 mg/day in reducing binge eating and purging in a placebo-controlled trial involving 387 bulimic women (Fluoxetine Bulimia Nervosa Collaborative Study Group 1992). One problem with medication given at times other than bedtime is that a significant amount may be purged through subsequent vomiting. Side effects and reasons for discontinuation of the various medications are similar to those observed in the treatment of depression. However, a study of bupropion found that a higher-than-expected proportion of patients developed grand mal seizures (Horne et al. 1988). The authors concluded that bupropion should not be used for the treatment of BN.

Overall, most antidepressants appear effective for the short-term treatment of BN, with little difference between them (Bacaltchuk and Hay 2003). An interesting recent study involving 47 patients with BN (Monteleone et al. 2005) examined the association of the 5-HTTLPR serotonin transporter genotype with antidepressant response, finding that those with the long form had a tenfold higher likelihood of attaining remission with a selective serotonin reuptake inhibitor (SSRI). As the authors pointed out, these results, if replicated, could allow therapists to prescribe SSRIs to those patients with BN who would be most likely to respond to these agents.

Less is known about the long-term effectiveness of medication. Three small-scale uncontrolled studies found that about one-third of the patients continuing antidepressant medication over periods of 6 months to 2 years relapsed (Pope et al. 1985; Pyle et al. 1990; Walsh et al. 1991). In a larger-scale examination of this issue, 147 women with BN who had decreased their vomiting by at least 50% while taking 60 mg of fluoxetine over an 8-week period were randomly allocated to continue medication or to be switched to placebo (Romano et al. 2002). A survival analysis found that the group receiving active medication experienced a longer time to relapse (or dropout) than did the placebo group. However, it should be noted that at the 3-month assessment, 55% of the fluoxetine group and 78% of the placebo group had either relapsed or dropped out of the study. At the 12-month follow-up, 83% of the fluoxetine group and 92% of the placebo group had experienced a relapse. The authors suggest that given these results, a multimodal

approach to the treatment of BN, including cognitive-behavioral therapy (CBT), should be considered.

To date, only one study has compared different lengths of antidepressant treatment, in this case with desipramine. Patients with BN treated for 16 weeks relapsed to pretreatment levels of binge eating when medication was withdrawn. On the other hand, those treated for 24 weeks maintained remission after withdrawal and at 1-year follow-up (Agras et al. 1991, 1994a). This study suggests that patients who respond to antidepressant treatment should be given a minimum trial of 6 months on medication. For the most part, however, controlled studies of antidepressants are of relatively short duration, as is the assessment of bulimic symptoms. Both of these factors may somewhat exaggerate the clinical efficacy of these medications.

Other Medications

Although considerable evidence from controlled trials indicates that most antidepressants are useful in the treatment of BN, few controlled studies of other pharmacological agents have appeared in the literature. However, topiramate (an anticonvulsant drug) has been evaluated in two controlled trials. In the first of these studies, patients meeting criteria for DSM-IV-TR bulimia nervosa were allocated at random to treatment with either topiramate (n = 35) or placebo (n = 34) over a 10-week period (Hoopes et al. 2003). Twenty-two (63%) of those in the topiramate group completed the trial, and topiramate was statistically superior in reducing binge eating and purging, and 22% of completers were recovered at the end of treatment. In the second study (Nickel et al. 2005), 30 patients with BN were randomly allocated to either topiramate or placebo. Topiramate was statistically superior to placebo in reducing binge eating and purging; however, no data on remission or recovery were reported. Although no direct comparison between topiramate and an antidepressant has been made, the data so far suggest that topiramate is about as effective as the antidepressants in the treatment of BN.

Combined Treatment

CBT for BN was developed in parallel with the use of antidepressants. CBT in either individual or group format has been shown to be more effective in reducing binge eating and/or purging than placebo (Mitchell et al. 1990), supportive psychotherapy plus self-monitoring of eating behavior (Agras et al. 1989), stress management (Laessle et al. 1991), behavior therapy (Fairburn et al. 1993), and psychodynamic forms of psychotherapy (Garner et al. 1993; Walsh et al. 1997). The existence of two different and effective treatments, antidepressant medications and CBT, naturally led to the question of whether the combined treatments would be more effective than either treatment alone.

The first study of this question used a randomized 2 x 2 design with four experimental groups: 1) imipramine combined with group psychosocial treatment, 2) imipramine with no psychosocial treatment, 3) placebo combined with group psychosocial treatment, and 4) placebo with no psychosocial treatment (Mitchell et al. 1990). Treatment was preceded by a single-blind placebo washout phase. One hundred and seventy-one women with BN entered treatment, which lasted for 10 weeks. The psychosocial treatment was an intensive group variant of CBT, with 5 daily sessions in the first week and 22 treatment sessions overall. The mean daily dosage of imipramine was 217 mg for the psychosocial treatment group and 266 mg for the group receiving medication alone. As might be expected, the dropout rate was significantly higher for those receiving medication (34%) compared with those taking placebo (15%). Imipramine was superior to placebo; however, CBT, with a remission rate of 51%, was superior to imipramine, with a remission rate of 16%, and combining the two treatments did not result in any additional advantage in reducing binge eating and purging. The combined treatment was, however, significantly superior to CBT in reducing depression.

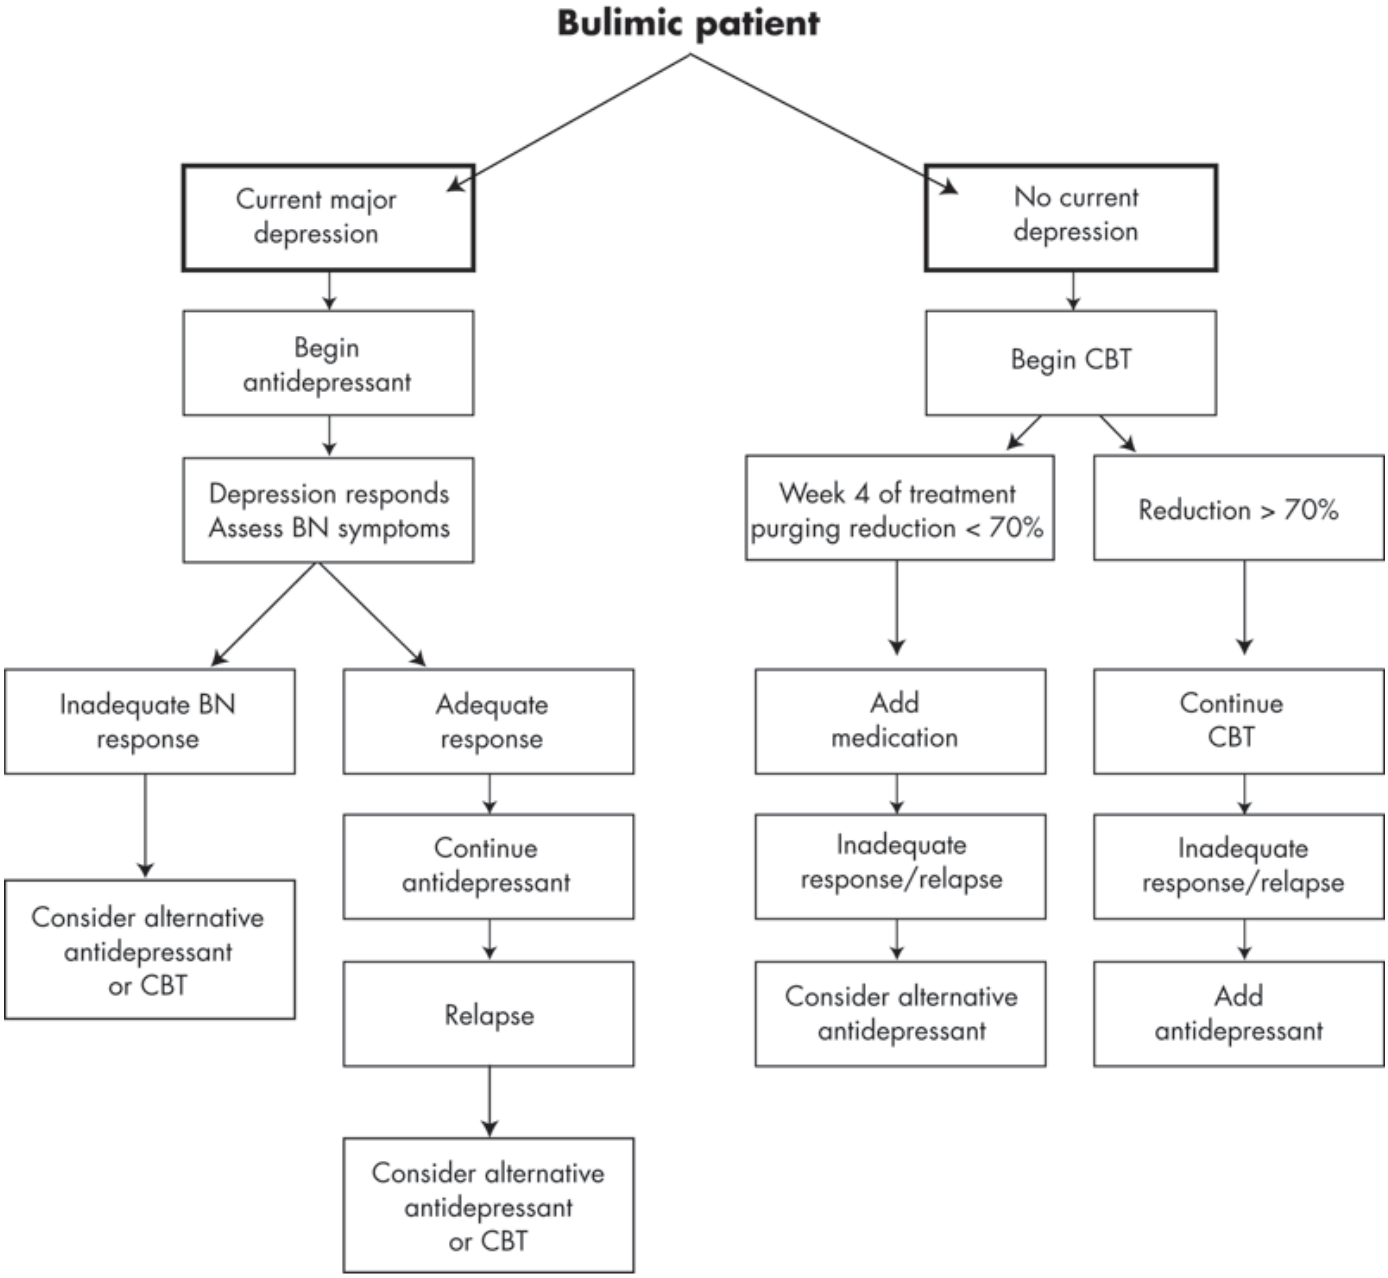
In the second study (Agras et al. 1991, 1994a), 71 participants were randomly allocated to one of three groups: 1) desipramine (mean daily dosage = 168 mg), 2) CBT, and 3) combined treatment. Half of the desipramine participants were withdrawn from medication at 16 weeks and the remainder at 24 weeks. CBT lasted for 24 weeks. Eighteen percent of the participants stopped taking desipramine before the end of treatment, compared with a treatment dropout of 4.3% of those participants receiving CBT. CBT, with a 48% remission rate, was significantly superior to desipramine, with a 33% remission rate, in reducing the frequency of binge eating and purging, and the combined treatment was no more effective than CBT alone. At 1-year follow-up of 61 of the original 71 patients, 77% of the combined treatment group were abstinent, compared with 54% of those receiving CBT alone (Agras et al. 1994a). This difference was not statistically significant. However, receiving desipramine alone for 24 weeks was the most cost-effective approach in terms of the cost of treatment per recovered patient at 1-year follow-up (Koran et al. 1995).

Another study involving 120 women with BN used a more sophisticated medication regimen consisting of desipramine followed by fluoxetine if the first medication was either ineffective or poorly tolerated (Walsh et al. 1997). It is important to note that the two-medication combination was used by two-thirds of the patients assigned to active medication, suggesting that a two-medication combination is closer to clinical reality than the use of a single medication. This study used a five-cell design: CBT combined with placebo or active medication, psychodynamically oriented therapy combined with placebo or active medication, and medication alone. CBT (plus placebo) was more

effective than psychodynamic therapy (plus placebo) in reducing both binge eating and purging. The average dosage of desipramine was 188 mg/day and of fluoxetine was 55 mg/day. Forty-three percent of the patients receiving medication dropped out of the study, compared with 32% of those receiving psychotherapy. Patients receiving active medication (in combination with psychological treatments) reduced binge eating significantly more than did those receiving placebo. Finally, antidepressant medication combined with CBT was superior to medication alone in reducing purging frequency. Of those receiving CBT plus medication, 50% were in remission, compared with 25% of those receiving medication alone. These findings suggest that the combination of CBT plus antidepressant medication may be the most effective approach to the treatment of BN. A meta-analysis confirmed this impression (Bacaltchuk et al. 2000).

Treatment After Psychotherapy Failure

In a small-scale double-blind, randomized, controlled trial, participants who had failed to respond to either CBT or interpersonal therapy in a multisite trial were randomly allocated to either fluoxetine 60 mg/day or placebo (Walsh et al. 2000). Twenty-three participants entered the study with a median of 22 binges and 30 purges over a 4-week period. Of those receiving fluoxetine, 38% were abstinent (over a 4-week period) at the end of treatment compared with none in the placebo group. This finding suggests that fluoxetine may be useful for those who do not respond to psychological treatments.



Comprehensive Treatment

Patients with BN are best treated as outpatients, unless there are either medical or psychiatric reasons for hospitalization (e.g., an intercurrent physical illness or a comorbid psychiatric disorder requiring hospitalization, such as major depression with suicidality). One reason that outpatient treatment is useful for the BN patient is that gains made in the hospital may not carry over to the patient's natural environment, where more complex food stimuli and greater stress are present than in the hospital.

The research evidence to date suggests that the combination of antidepressant medication and CBT is likely to be somewhat more effective than either therapy alone. Because CBT is more effective than antidepressant medication, having fewer dropouts than medication, in the ideal case, this should be the first therapy offered to the patient. However, CBT is not always available, and in such circumstances, medication will be the only choice. In addition, patient preferences for one or another treatment should be taken into account.

The flow chart in Figure 59–1 presents an algorithm as guidance to the overall treatment of BN. The first decision to make is whether the patient has current major depression, which is seen in approximately 25% of bulimic patients presenting for treatment. Because depressive symptoms can interfere with the conduct of CBT for BN, antidepressant medication should precede CBT in such patients. When the patient has sufficiently recovered from depression, the eating disorder should be reevaluated. If the patient has not recovered from the eating disorder, then CBT should be added.

CBT = cognitive-behavioral therapy.

As shown in Figure 59–1, after 4 weeks (six sessions) of therapy, if the reduction in purging with CBT is less than 70%, an antidepressant should be added. This algorithm is based on the findings of a multisite study involving 194 women with BN, which found that the initial treatment response to CBT predicted outcome reasonably well (Agras et al. 2000). Those reducing purging less than 70% after 4 weeks of treatment were more likely to be nonresponders. If there is an inadequate response to antidepressant treatment or a relapse, an alternative antidepressant should be used. For those who complete CBT with insufficient improvement, despite having reduced their purging at session 6, then an antidepressant should be advised.

BINGE-EATING DISORDER

Although the association between binge eating and obesity has been noted from time to time in case reports in the literature, it was not until the upsurge of research into the psychopathology and treatment of BN that systematic attention was paid to BED. The principal features of BED are episodes of binge eating at a frequency of at least 2 days a week for 6 months, marked distress caused by binge eating, and binge eating that does not occur during the course of BN or AN. Purging does not occur in this condition, although about 10% of the patients with BED have a history of BN.

Between 1% and 2% of women in the general population meet criteria for BED (Bruce and Agras 1992). In clinical populations, the ratio of women to men with BED is approximately 3:2, the highest rate for men for any eating disorder. Although obesity is not a requirement for the diagnosis of BED, there is a substantial overlap between BED and obesity. Studies have shown that about one-quarter of obese subjects have symptoms that meet criteria for BED and that the prevalence of binge eating increases as body mass index increases (Marcus et al. 1985; Spitzer et al. 1993; Telch et al. 1988). Because binge eating often precedes the onset of becoming overweight, binge eating may be a risk factor for obesity and the multiple health problems associated with being overweight. Moreover, the syndrome is associated with comorbid psychopathology similar to that of BN and causes much distress; hence, it is an entity deserving of treatment in its own right. One study that compared individuals with BED with weight-matched non-binge-eating obese individuals found that subjects with BED were significantly more likely to receive diagnoses of major depression (51%), panic disorder (9%), and borderline personality disorder (9%) than were those without BED (Yanovski et al. 1992).

Pharmacological Treatment

Antidepressants

Double-blind, placebo-controlled studies suggest that antidepressants are at least as useful in the treatment of BED as in BN. Early placebo-controlled studies found desipramine to be effective in reducing binge eating, with an abstinence rate of 60% (McCann and Agras 1990). Studies of SSRIs suggest moderate efficacy for fluoxetine, sertraline, and citalopram (Appolinario and McElroy 2004; McElroy et al. 2000). Other studies have found no effect for fluoxetine on binge eating (Devlin et al. 2005; Grilo et al. 2005b). These conflicting results may be due to the relatively high placebo response observed in some studies. There has also been considerable variability in weight losses experienced by patients with BED treated with antidepressants, from essentially no weight loss to several pounds. Although the McCann and Agras (1990) study found that antidepressants reduced binge eating, patients who stopped binge eating did not lose weight. In another controlled study, 108 overweight women with BED received 3 months of CBT, followed by 6 months of weight-loss treatment combined with desipramine. No additive effect of desipramine on binge eating was found; however, women in the medication group lost significantly more weight (4.8 kg) than those in the comparison group (Agras et al. 1994b).

The serotonin–norepinephrine reuptake inhibitor sibutramine (15 mg/day) and the selective norepinephrine reuptake inhibitor reboxetine (8 mg/day) also appeared to be useful in the treatment of BED in open-label studies (Shapira et al. 2000; Silveira et al. 2005). Weight losses were relatively large with both of these medications. A placebo-controlled study of sibutramine in 60 obese women with BED confirmed these early studies (Appolinario et al. 2003), with 52% achieving abstinence from binge eating compared with 32% in the placebo group. Weight losses were 7.4 kg for the sibutramine group compared with a small increase in weight for the placebo group.

Other Medications

Anticonvulsants such as topiramate and zonisamide also appear useful in the treatment of BED (McElroy et al. 2006). A multisite study in which more than 400 participants with BED were allocated at random to either topiramate or placebo provided further evidence of the efficacy of topiramate (McElroy et al. 2007). The median dosage of topiramate was 300 mg/day. Dropouts were equivalent between groups (29% topiramate; 30% placebo). Fifty-eight percent of those in the topiramate group and 29% in the placebo group were in remission at the end of the study period. The mean weight loss was 4.5 kg in the topiramate group versus a small gain in the placebo group. The most common side effects specific to topiramate were paresthesia and difficulty concentrating. Hence, topiramate leads to a reasonable rate of remission combined with substantial weight loss.

Finally, a placebo-controlled study comprising 50 overweight participants with BED compared orlistat (120 mg three times daily) with placebo, both groups receiving an abbreviated form of CBT (Grilo et al. 2005a). At the end of treatment, 64% of those in the orlistat group and 36% of those in the placebo group were in remission. The proportions achieving at least a 5% weight loss were 36% for orlistat and 8% for placebo. However, after discontinuation of both treatments, there was no difference in abstinence rates between groups (52% in both groups).

Comprehensive Treatment

BED presents three problems to the clinician: binge eating, overweight, and comorbid psychopathology, particularly depression. Hence, a comprehensive treatment should address all of these problems. There are few direct comparisons of psychotherapy and medication, and the situation is further complicated by the larger placebo responses found in BED as compared with BN, probably accounting for the lack of efficacy of pharmacological agents in some studies. For patients who prefer to try medication, it appears on present evidence that sertraline and topiramate are the most effective in terms of reducing both binge eating and weight. Less is known about medications that may add to the

effects of psychotherapies such as CBT and interpersonal therapy, both of which are associated with substantial reductions in binge eating that appear to be well maintained, although weight losses are small. Hence, it appears reasonable to augment psychotherapy with either sertraline or another SSRI, topiramate, or orlistat.

ANOREXIA NERVOSA

AN is a relatively rare disorder characterized by marked weight loss (at least 15% below ideal body weight), intense fear of gaining weight, disturbance in the experience of body shape (i.e., feeling fat in the face of marked weight loss), and (in females) amenorrhea. It is the most lethal psychiatric disorder. Follow-up studies document an aggregate mortality rate of about 5.6% per decade; about half of these deaths are a result of suicide, and the remainder are largely due to cardiovascular instability (Casiero and Fishman 2006). Because of the chronicity of the condition, it has become apparent that identification and treatment of the disorder early in its course are essential. A specific family therapy for adolescents that aims to help parents take charge of their child's eating appears to be successful in both the short and the long term, with about 70% of adolescent patients with anorexia recovered both at the end of treatment and at follow-up (Lock et al. 2005, 2006).

Most patients with anorexia can be treated as outpatients. However, treatment can be difficult because of the patient's reluctance to gain weight. Weight should be monitored at every outpatient visit, and it is important that weight be measured in a hospital gown to prevent the use of lead weights to which some patients with anorexia resort. Other methods of inflating weight are less easy to detect, such as drinking large quantities of water before being weighed. Indications for hospitalization include weight less than 75% of ideal body weight for age and height, heart rate below 40 beats/minute, blood pressure below 90/60 mm Hg, potassium levels below 3 mEq/L, temperature below 97°F, and very rapid weight loss. In addition, because of the associated psychopathology in this disorder, the usual indications for hospitalization for severe psychopathology should be followed.

Because the disorder is rare, it is difficult in any one center to acquire an adequate sample size for a study in a reasonable time; thus, satisfactory randomized, double-blind medication trials are difficult to accomplish. Moreover, medication trials should be long enough and use optimal medication dosages to adequately show effects in this chronic relapsing disorder. Unfortunately, few trials meet these criteria; many are of short duration, use inadequate dosages of medication, or have been carried out in inpatients.

Pharmacological Treatment

Most studies of antipsychotic agents in the treatment of AN, including chlorpromazine, pimozide, and sulpiride, showed no evidence of efficacy (Dally and Sargant 1960; Vandereycken 1984; Vandereycken and Pierloot 1982). Recent case reports, however, suggest that risperidone may lead to weight gains (Newman-Toker 2000). The effects of olanzapine were studied in 34 patients with anorexia nervosa receiving day care treatment who were allocated to active drug or placebo. The mean dosage of olanzapine was 6.61 mg/day. Those allocated to olanzapine recovered more quickly than those on placebo and gained about 0.6 kg more than those on placebo. Obsessive thinking was also decreased in those receiving olanzapine, but there were no other differences in psychopathology between groups (Bissada et al. 2008). Further studies with larger sample sizes are needed. Moreover, the clinical impression is that olanzapine is not well accepted by patients with AN.

An important study found that fluoxetine was not effective in hospitalized patients with AN (Attia et al. 1998). In this study, 31 women hospitalized with AN participated in a 7-week randomized, double-blind trial of fluoxetine at a mean dosage of 56 mg/day. Four patients in each group terminated the trial early. Although all patients in the study showed improvement, no significant differences were seen between active medication and placebo. In addition, there was no apparent effect of medication on depression or obsessional symptoms. This study suggested that fluoxetine had no effect over and above that of an inpatient program and adds to the consistent failure to show a beneficial effect of antidepressant medication during the period of weight regain.

Despite the findings of an earlier small-scale outpatient study (Kaye et al. 2001), a more recent study of 93 adult outpatients found no benefit of fluoxetine in either promoting weight maintenance or prolonging time to relapse in a double-blind, placebo-controlled trial (Walsh et al. 2006a). As is usual in this population, there was a large proportion of dropouts or early terminations from treatment (51% of fluoxetine-treated and 63% of placebo-treated patients). A fairly high proportion of patients were dissatisfied with treatment. The very high dropout rates make a statistical comparison between groups difficult because of the large amount of data being carried forward in an intent-to-treat analysis. Nonetheless, the only difference between groups was a statistical advantage for fluoxetine in reducing anxiety levels.

Given the findings that fluoxetine confers no benefit for adult patients with AN either during the weight gain period in hospital or during outpatient treatment, one must conclude that the use of fluoxetine is not indicated in the treatment of AN except for the treatment of comorbid psychopathology. At this point, however, there have been no satisfactory

studies of SSRIs in adolescents with AN, and such studies would appear warranted given the high priority for treatment early in the course of AN.

CONCLUSION

The place of psychopharmacological agents in the treatment of BN has been well worked out. Treatment with sequential trials of different antidepressants should result in abstinence rates of about 40%. The addition of CBT enhances the effectiveness of antidepressants. It is becoming clear that agents such as topiramate and similar anticonvulsants are useful in the treatment of BED, with the added advantage of facilitating substantial weight loss in the overweight patient. In the case of AN, there is little evidence that pharmacological agents are helpful in either inpatient or outpatient treatment of the adult patient, except to treat comorbid psychiatric disorders. There is insufficient information regarding adolescent anorexia to provide guidance regarding the use of medication at this point.

Chapter 60. Treatment of Insomnia

TREATMENT OF INSOMNIA: INTRODUCTION

Our conceptualization of insomnia has undergone a dramatic shift during the past few years, from an annoying but not particularly serious symptom to the recognition that 1) sleep loss from any cause has serious consequences, 2) chronic insomnia and the impaired sleep it represents are highly comorbid with (or indeed may cause) many other medical and psychiatric disorders, and 3) chronic insomnia in some cases may represent a separate medical disorder in itself, with an independent neurobiological basis. It has been suggested that certain chronic insomnias be considered on a par with depression as a serious disorder with a tendency toward chronicity whose treatment needs independent assessment and possibly long-term management (Jindal et al. 2004). This increase in complexity is in part offset by improved treatment options, both pharmacological and nonpharmacological. This chapter will review these areas in what we hope is a clinically useful manner.

MORBIDITY OF INSOMNIA AND CONSEQUENCES OF SLEEP LOSS

The 2005 National Institutes of Health (NIH) Consensus Conference on Chronic Insomnia in Adults estimated that 30% of the general population has symptoms or complaints consistent with insomnia (http://consensus.nih.gov/2005/2005InsomniaSOS026html.htm). The symptoms of insomnia may include complaints of not being able to get to sleep, not being able to stay asleep, waking too early, or sleep that is not refreshing—and often a combination of the foregoing. Individuals with insomnia report diminished quality of life, including impaired concentration and memory, decreased ability to accomplish daily tasks, decreased ability to accomplish daily tasks, and decreased ability to enjoy interpersonal relationships (Ancoli-Israel and Roth 1999). Untreated insomnia is associated with increases in new-onset anxiety and depression, increased daytime sleepiness, and increased health-related concerns (Richardson 2000), as well as increased use of health-related services (Novak et al. 2004). Patients with primary insomnia demonstrate impaired memory consolidation during sleep (Backhaus et al. 2006), and recent evidence suggests they may have diminished hippocampal volumes (Riemann et al. 2007).

New data on the effects of sleep loss in otherwise healthy adults affirm the importance of adequate sleep. Going without sleep for 17–21 hours, not uncommon in many occupations and life situations, may lead to psychomotor performance decrements similar to those seen with legal alcohol intoxication (Dawson and Reid 1997), which may not be apparent to the individual concerned. Going without sleep for a single night following a hepatitis A immunization may lead to a 50% reduction in hepatitis A antibody formation a month later (Lange et al. 2003). Relatively mild sleep loss may result in significant decline in cognitive performance, and sleep restriction to 4 hours per night for 2 nights in healthy males has been shown to decrease leptin and increase ghrelin production, with potentially adverse effects on the potential to develop obesity (Spiegel et al. 2004). Both short-term total and partial sleep deprivation have been shown to increase C reactive protein levels in otherwise healthy adults (Meier-Ewert et al. 2004). Although an insomnia complaint is not isomorphic with sleep deprivation, individuals with insomnia have been shown to get less sleep and therefore are at greater risk for the adverse events accompanying sleep deprivation. Data are emerging suggesting a relationship between sleep loss and the development of both insulin resistance and the individual

components of the metabolic syndrome (Wolk and Somers 2007), an issue of special concern in an American population thought to be generally mildly sleep deprived and in which obesity and type 2 diabetes are serious public health issues.

We now recognize that the insomnia complaint may reflect dysfunction of several underlying neurobiological systems supporting sleep, including the homeostatic Process S and circadian Process C systems, as well as influences from comorbid medical and/or psychiatric conditions and the effects of environmental stress and poor sleep habits. Quite often, several of these factors interact to produce the insomnia-based symptom complex that patients present with, a circumstance that serves to highlight the importance of accurate and comprehensive differential diagnosis of an insomnia complaint before embarking on treatment.

This chapter advances the position that most patients with insomnia complaints can be helped if sufficient attention is paid to accurate differential diagnosis, with recognition and appropriate treatment of their underlying pathologies contributing to their complaints.

SLEEP ARCHITECTURE

Sleep architecture refers to the characteristic scalp electroencephalogram (EEG) patterns that characterize the different waking and sleep states (wakefulness, rapid eye movement [REM] sleep) and non-REM sleep stages (1 through 4). EEG rhythms are defined primarily by their frequency in cycles per second (termed Hertz [Hz]), with the major frequency bands being delta (<4 Hz), theta (>4 to <8 Hz), alpha (~8 to ~12 Hz), beta (~13 to ~20 Hz), and gamma (>20 Hz). Sometimes 12- to 14-Hz "sleep spindle" activity is termed ***sigma*** activity.

Wakefulness is normally accompanied by what is termed a "low-voltage, fast" scalp-recorded EEG, with frequencies usually greater than 8 Hz and amplitudes in the vicinity of 50 μV or less. The most prominent EEG rhythm of quiet, relaxed wakefulness is the so-called alpha rhythm, seen over the top and back of the head (visual receptive regions) when the eyes are closed. Alpha rhythm consists of rhythmical 8- to 12-Hz activity, usually about 50 μV in amplitude.

The transition from wakefulness to sleep—normally Stage 1 non-REM sleep—is indicated by the appearance in the EEG of slower 5- to 7-Hz theta activity of generally low voltage. The subject is not responsive at this point but can be easily aroused. Stage 1 sleep usually constitutes only about 5%–7% of total sleep time.

After a few minutes, the typical subject transitions into Stage 2 sleep, characterized by further slowing of the EEG and the appearance of sleep spindles and K complexes. Spindles are short (usually <1 second) bursts of 12- to 14-Hz activity dominant over high central regions that wax and wane in amplitude—hence the term ***spindle.***

Stage 3 and Stage 4 sleep usually follow Stage 2 and are characterized by increased slowing and increased amplitude of the EEG. Stage 3 sleep contains between 20% and 50% of high-voltage (>75 mV) slow (<2 Hz) delta activity, and Stage 4 sleep contains >50% slow delta activity. Stage 3 and Stage 4 sleep are often grouped together and termed ***delta sleep*** or slow-wave sleep (SWS). Stage 3 and 4 sleep constitute about 20%–25% of sleep time in adults, but that percentage is higher in adolescents and lower in healthy elderly individuals as well as in many pathological conditions, including depression, schizophrenia, and many insomnia disorders. Older individuals may have slow-wave delta activity, but it is not of sufficient amplitude (75 μV) to be formally scored as Stage 3 or 4.

After the typical adult has been asleep (in non-REM sleep) for about 90 minutes, the EEG transitions to a lower-voltage, faster pattern. The subject remains asleep, but the eyes can now be seen rapidly moving beneath the closed lids. Consequently, this stage of sleep is called rapid eye movement or REM sleep. If awakened during this stage, the subject will often report dreaming. The time from sleep

onset (i.e., Stage 1) to the onset of the first REM period is termed *REM latency,* which has diagnostic implications. In some psychiatric disorders (e.g., major affective disorders, schizophrenia, and eating disorders), and occasionally in narcolepsy, REM latency is shorter than normal. REM latency tends to decrease with advancing age, but, as a rule of thumb, nocturnal REM latency of less than 60 minutes in an adult should be considered unusually short and might suggest a major affective disorder. REM sleep usually constitutes about 20% of total sleep time in adults.

Until very recently, conventional EEG sleep scoring was still largely based on the sleep atlas of Rechtschaffen and Kales (1968), which dates from the time that sleep records were recorded on paper EEG machines, usually run at a speed of 10–30 mm/second, and included only those EEG frequencies easily visible to the naked eye (very low [<0.5 Hz] and very high [>50 Hz] frequencies were usually not recorded). We can probably expect some significant revisions in scoring techniques in the near future based on availability of computerized EEG recording and analytical techniques. Altered sleep morphology not captured by conventional scoring includes the presence of "cyclic alternating patterns" that appear during sleep and may be associated with daytime fatigue (Guilleminault et al. 2006), computer quantification of slow-wave activity indexing sleep drive and/or quality (Armitage et al. 2007), and the presence of very-high-frequency (gamma-band) EEG activity (Perlis et al. 2001a, 2001b). Such issues have begun to be addressed in "The AASM Manual for the Scoring of Sleep and Associated Events: Rules, Terminology and Technical Specification," recently published by the American Academy of Sleep Medicine (2007).

SLEEP PHYSIOLOGY AS IT RELATES TO INSOMNIA

It is necessary to have a basic understanding of the neurobiological mechanisms underlying sleep if we are to understand insomnia.

Perhaps the most basic issue is that there are fundamentally two quite different types of sleep, non-REM and REM, each with its own neuroanatomy, physiology, function, developmental course across the life span, and pathologies. These differences are summarized in Table 60–1.

TABLE 60–1. Characteristics of non-REM and REM sleep

	Non-REM sleep	REM sleep
Neuroanatomy	Basal forebrain, VLPO neurons	Pontine tegmentum
Physiology	↓HR, ↓RR, ↓BP, ↓BT, ↓EMG	↕HR, ↕RR, ↕BP, poikilothermic, ↓↓↓↓EMG
Control mechanism	Process S and Process C	Independent pontine oscillator
Developmental course across life span	Appears during first year, ↑ in early adolescence, then stabilizes in adulthood	High at birth, decreases by age 6 years to adult levels
Function	Neurometabolic restoration, synaptic pruning	Early mammalian brain development
Pathologies	Insomnia, parasomnias, hypersomnias	Nightmares, RBD, narcolepsy

Note. ↑ = increased; ↓ = decreased; ↓↓↓↓ = very greatly decreased; ↕ = highly variable.
BP = blood pressure; BT = body temperature; EMG = electromyograph; HR = heart rate; REM = rapid eye movement; RBD = REM sleep behavior disorder; RR = respiratory rate; VLPO = ventrolateral preoptic area.

At any single point in time, the brain will usually be in only a single "state"—that is, either awake, in non-REM sleep, or in REM sleep. Admixtures of state, however, are possible and usually present as unusual sleep pathologies. For example, "sleep paralysis" and cataplexy are admixtures of REM sleep and awake. Sleepwalking is an admixture of partial (motor—not conscious) arousal and non-REM sleep. The major indicator of what state we are in is the type of EEG patterns and related physiological

and behavioral activity present at the moment.

A second basic issue is that we usually conceptualize sleep as reflecting the balance of two fundamental processes—Process S, a homeostatic process in which the tendency to go into non-REM sleep is increased by previous time awake, and Process C, a circadian arousal process that tends to offset Process S so that we don't go to sleep until we are ready to—that is, when 1) Process S has built up and 2) the Process C arousal tendency begins to decrease.

These different types of sleep and control processes should become clearer as we outline them in the following sections.

Wakefulness, Non-REM Sleep, and the Biology of Process S

The neuronal systems that regulate our daily cycle of sleep and wakefulness, while quite complex, are becoming better defined. Discovery of the ascending reticular activating system (ARAS), a wakefulness-promoting neurophysiological circuit that originates in the lower and more central parts of the brain, was based in part on von Economo's observations of brain pathology in individuals who died of the epidemic of sleeping sickness or encephalitis lethargica that was seen in Europe and the United States in the early twentieth century. Mediated through two major pathways, one to the thalamus and a second more direct one to the hypothalamus and cortex, these cell groups when active promote wakefulness. The ARAS depends significantly on acetylcholine and monoamines, as well as other neuropeptide neurotransmitter systems.

A second set of competing systems located primarily in hypothalamic and contiguous regions, and emphasizing neuronal activity in the ventrolateral preoptic (VLPO) region of the hypothalamus, promotes non-REM or slow-wave sleep and inhibits wakefulness. These neuronal systems depend significantly on the inhibitory neurotransmitters galanin and γ-aminobutyric acid (GABA) (which most hypnotics are thought to modulate). Cells in the VLPO system appear to be activated by a buildup of adenosine secondary to duration of preceding wakefulness (Basheer et al. 2004). The longer a person has been awake, the more likely it is that sleep will be triggered, and the adenosine antagonist caffeine tends to prolong wakefulness.

Although the ARAS and the VLPO system are competing (increased activity in one decreases activity in the other), normally only one system at a time is predominant, for as a rule we are either awake or asleep and spend relatively little time in intermediate (and biologically less useful states) states. This suggests from an engineering view a type of biological flip-flop switch. Recent research indicates that such a switch may indeed exist, mediated by the lateral hypothalamic neuropeptides orexin and hypocretin, serving the function of a stabilizing system to keep the brain in either a wakeful or sleep state and preventing rapid oscillation from one state to the other (Saper et al. 2005). The role of orexin in modulating the sleep–wake system is not yet well understood, although preliminary animal studies suggest orexin antagonists induce sleep in animals and humans (Brisbare-Roch et al. 2007).

The REM State

REM sleep constitutes the third major physiological state (wakefulness and slow-wave sleep being the others), with neuronal generating and control systems essentially independent of wakefulness and non-REM or slow-wave sleep. The REM state is uniquely different from either wakefulness or slow-wave sleep, may include elements of both, yet may be independent of both.

Brain stem neuronal systems that have independent oscillation frequencies appear to account for the periodic generation of the REM state in all mammals, including humans. These systems largely reside in the pontine tegmentum and may constitute a separate component of the ARAS. The periods of these independent oscillations appear to be a function of body size, being approximately 2 hours in elephants, 90 minutes in humans, 60 minutes in Old World monkeys, 30 minutes in cats, 12 minutes in rats, and 6 minutes in mice. Cholinergic systems appear involved in activating REM states, and

monoamines in suppressing them. Agents that increase acetylcholine (ACh) activity, such as the acetylcholinesterase inhibitor physostigmine, increase REM sleep, and agents that increase monoamine activity, such as monoamine oxidase–inhibiting antidepressants, decrease REM sleep. It has recently been suggested that a type of neurophysiological toggle switch also exists for controlling transitions into and out of the REM state, consisting of mutually inhibitory neuronal populations that are GABA-ergic in nature, with independent pathways mediating EEG and atonia effects (Lu et al. 2006). This switch is thought to be subsidiary to the putative wake–sleep toggle switch, preventing transitions into REM during wakefulness, absent pathologies such as narcolepsy, which is thought to involve a weakened wake side of the wake–sleep switch due to loss of orexin neurons. Such a model would help explain a number of disorders in which impaired REM regulation is seen.

Process C: Circadian Physiology and Sleep

A second major neurobiological system controlling the timing of sleep is termed Process C (for circadian).

Like most living organisms, humans have prominent daily, or circadian, biological rhythms, which have important implications for normal sleep regulation and sleep disorders. The body's major circadian oscillator is located in the suprachiasmatic nucleus (SCN) of the hypothalamus. The SCN can oscillate independently, and animal studies suggest that separate genes control the phase, period, and amplitude of its oscillations. Recent studies have linked specific human circadian clock genes to circadian-based sleep disorders (Hamet and Tremblay 2006). The SCN controls many biological rhythms, including those of body temperature, various hormones, and the sleep–wake cycle, or perhaps more precisely the circadian alerting tendency, which is here termed Process C. This rhythm appears coupled to the temperature rhythm, with higher body temperatures being associated with an increased tendency to wakefulness, and vice versa.

The normal sleep–wake rhythm is a 24-hour rhythm that is usually synchronized to the circadian temperature and cortisol rhythm. The sleep–wake rhythm may become desynchronized when the sleep–wake schedule is abruptly changed (as occurs with a rapid time zone shift), during which the circadian oscillator initially remains on its original schedule. This desynchrony between the attempted sleep–wake schedule in the new time zone and the underlying circadian rhythm is one cause of "jet lag."

Human subjects who live in caves or other dimly lit, time cue–free environments will typically adopt a sleep–wake rhythm of approximately 24.2 hours (Czeisler et al. 1999). This suggests that the normal free-running circadian period is slightly longer than 24 hours and must be "phase advanced" about 12 minutes each day to stay in synchrony with the 24-hour rhythm of the sun. Overall, it appears easier to phase-delay than to phase-advance the body's rhythms, since a phase delay is going in the "direction" of a free-running rhythm. This has practical implications in the adaptation to a new time zone. A phase delay, as in East-to-West travel (with a later bedtime), is generally easier and more quickly adjusted to than a phase advance, such as when going West to East (with an earlier bedtime).

Light is a major synchronizer of circadian rhythms, and it has become apparent that, as in most other organisms, circadian rhythms in humans can be reset by appropriately timed exposure to bright light (Czeisler et al. 1986). Recent evidence suggests that short-wavelength light (shifted toward the blue end of the spectrum; wavelength ~460 nm) is more effective at modulating the activity of the SCN compared to longer-wavelength light (Lockley et al. 2006). The phase–response curve (PRC) plots how the timing of light exposure affects circadian rhythm timing. The human PRC suggests that exposure to bright light immediately before or shortly after onset of the sleep period (i.e., typically in the late evening) will tend to delay the circadian system, whereas exposure late in the sleep period, shortly before or after awakening (i.e., early morning), will tend to advance the circadian system. Light sensitivity may be related to the time of the lowest body temperature (the "nadir" of the body

temperature circadian rhythm), with light exposure just prior to the body temperature nadir phase delaying the circadian rhythms and light exposure just after the nadir phase advancing the circadian rhythms. The human PRC provides useful information for timing the use of bright-light exposure as a therapeutic modality for treatment of jet lag or circadian rhythm disorders resulting from shift work.

The hormone melatonin, secreted by the pineal gland at night, appears to influence circadian rhythms. Its secretion is regulated by light information relayed to the pineal gland from the SCN. Melatonin secretion can be blocked by exposure to bright light during normally dark times. There is emerging evidence that melatonin can be used to reset the circadian system, to treat circadian rhythm disorders, and possibly to treat jet lag and work shift change (Brzezinski 1997), although it generally does not work well as a hypnotic agent. Although the therapeutic use of melatonin is receiving considerable media attention, it has been classified as a food supplement and is available over the counter.

The take-away point here is that both Process S and Process C have specific biological underpinnings, and pathologies in either or both can result in disturbed sleep and complaints of insomnia. Part of the differential diagnosis of insomnia is attempting to separate the two systems in terms of their independent contribution to the complaint, as this impacts treatment.

Functions of Sleep

Sleep is a function of the brain and is thought to support proper brain function. Emerging data clearly suggest sleep has a major role in both memory consolidation and brain (synaptic) plasticity (Walker and Stickgold 2006). Sleep spindle activity has been related specifically to improved memory recall performance (Clemens et al. 2005; Schabus et al. 2004), and very localized increases in very slow delta activity during sleep has been related to performance improvement in sleep-dependent learning of motor tasks, supporting its role in synaptic "pruning and tuning" (Huber et al. 2004).

Sleep is likely intimately related to regulation of overall energy metabolism as well, as suggested by the effect of mild sleep restriction on changes in leptin (decreases) and ghrelin (increases) production (Spiegel et al. 2004). Both sleep restriction and excessive sleep have been reported as risk factors in the development of insulin resistance and type 2 diabetes (Yaggi et al. 2006), and it has been postulated that chronic sleep loss may be a risk factor for obesity and insulin resistance, as well as type 2 diabetes (Chaput et al. 2008; Gangwisch et al. 2007; Spiegel et al. 2005).

The role of REM sleep in adult animals remains to be clearly defined, but its role in the development of the immature mammalian brain seems apparent, specific mechanisms notwithstanding. Human newborns have about 50% REM sleep, and human premature infants 80%. Newborn infants of altricial mammals like rats and cats have greater percentages of REM sleep than adult animals, while newborn infants of precocial animals like guinea pigs have lower adultlike levels of REM sleep at birth. It has been suggested that the periodic ascending brain activation associated with REM sleep may be important in developing species-appropriate neuronal pathways in the developing brain. Its role in adult animals has been postulated as involving learning and memory functions, but studies to date are inconclusive in this regard.

THE INSOMNIA COMPLAINT

The duration of an insomnia complaint has a major impact on its differential diagnosis and treatment. Transient and short-term insomnias are usually stress- or environmentally related, and the cause is obvious. Although they rarely come to the attention of health care providers, their treatment is also generally straightforward, and they should, as a rule, be treated when found to prevent them from becoming more chronic. The chronic insomnia complaint requires a more systematic differential diagnosis procedure, also fortunately usually fairly straightforward. We first consider the transient and short-term complaint and then move on to a discussion of the chronic insomnia complaint.

Transient and Short-Term Insomnias

Transient (several days) and short-term (several weeks) insomnias are quite common. Most individuals experience short-term trouble with sleep latency or sleep maintenance at times of stress, excitement, or anticipation; during an illness; after going to high altitudes; or accompanying sleep time changes (e.g., shift work, jet lag). Such problems rarely come to the attention of the clinician in the early stages, although, of course, clinicians will experience these problems themselves. Symptoms of insomnias can nonetheless be decreased, and daytime functioning improved, if certain guidelines are followed. Stress-related insomnia, or temporary trouble sleeping in response to excitement or worry (e.g., anticipating a trip or a forthcoming interview or examination), may appropriately be treated with a night or two of a short-half-life hypnotic agent (e.g., zolpidem 5 or 10 mg at bedtime). This medication need not necessarily be taken in anticipation of trouble sleeping; it can be placed at the bedside and taken only after the patient has been unable to fall asleep for 30–60 minutes, because it has a rapid onset and relatively short duration of action. Awakening in the middle of the night with inability to fall asleep again can be treated with zaleplon 10 mg (half-life approximately 1 hour), as long as at least 4 hours are still available for sleep.

Short-term insomnias are due to more serious and prolonged stressful situations and may last up to several weeks. The concern is that, if not treated, a conditioned or learned insomnia may develop in response to concerns about not being able to go to sleep that can result in a more chronic insomnia.

The appropriate treatment of transient and short-term insomnia not only improves daytime performance but also may prevent the insomnia from developing into a chronic problem. There is no reason that responsible patients who know they are susceptible to transient insomnia in relation to predictable stressful events cannot have a hypnotic agent available to use prophylactically. Bereavement is often associated with a short-term insomnia, which has been reported to respond favorably to sedative tricyclic agents (Pasternak et al. 1991).

Altitude-Related Insomnia

Altitude-related insomnia may occur when individuals rapidly travel to higher altitudes, such as skiing and mountain climbing trips. High-altitude insomnia results primarily from periodic breathing with increases in sleep-related central apneas and hypopneas, which can be diminished by several days' administration of acetazolamide (125 mg once or twice a day). Acetazolamide also appears to decrease risk of developing altitude sickness. A short-acting hypnotic may also be useful for several nights. It has been demonstrated that both zaleplon (10 g) and zolpidem (10 mg) improve sleep quality at altitude without adverse effects on respiration, attention, alertness, or mood (Beaumont et al. 2007). Altitude-related insomnia normally improves spontaneously after several days, at least at altitudes below 15,000 feet. Altitude-related sleep problems can also be seen in infants but normally resolve spontaneously without specific treatment after the first night (Yaron et al. 2004).

Shift Work– and Jet Lag–Related Insomnia

Attempts to sleep at times substantially different from what one is accustomed to, commonly associated with long-distance travel (jet lag) or shift work, often result in disrupted sleep and insomnia complaints. In both cases sleep is being attempted when the Process C system may be in the high arousal state, and wakefulness may be necessary when the Process C is in the low arousal state. In both shift work– and jet lag–related insomnia, there can be significant problems with both sleep and wakefulness.

Shift work is the more serious of the two since it is often prolonged and is known to be associated with health and performance impairments. More than 6 million Americans work night shifts on a regular or rotating basis, and shift work sleep disorder is common in this group, with increased incidence of gastrointestinal and cardiovascular disorders and impaired family and social functioning, as well as an

increased risk of accidents (Schwartz and Roth 2006). When working shifts is necessary, efforts must be made to preserve sleep as much as possible as well as to maintain wakefulness during the work period. Such efforts can be both pharmacological and behavioral. Modafinil (200 mg) has been shown to help maintain wakefulness during work hours, but because it has a relatively long half-life (~12–15 hours), it should be taken early so as not to interfere with later sleep. The use of hypnotics to improve sleep during the sleep period must be considered in terms of the risk–benefit ratio. Bright light early during the work period, with protection from bright light late in the work period and on the way home in the morning, can help with subsequent sleep (Schwartz and Roth 2006).

Jet lag also involves travel-related rapid time zone changes such that waking activities are required during the circadian sleep time and sleep is required during the circadian wake time. Symptoms are due both to this circadian desynchrony and sleep loss. Paying proper attention to light exposure following transoceanic travel and remembering that initially the circadian system responds to light as though it is still on the time zone one departed from can facilitate rapid entrainment to the new light–dark schedule. Protection of sleep with short-acting hypnotic agents during the new sleep periods for the first few nights can be helpful, as is appropriate supplemental melatonin administration (Cardinali et al. 2006).

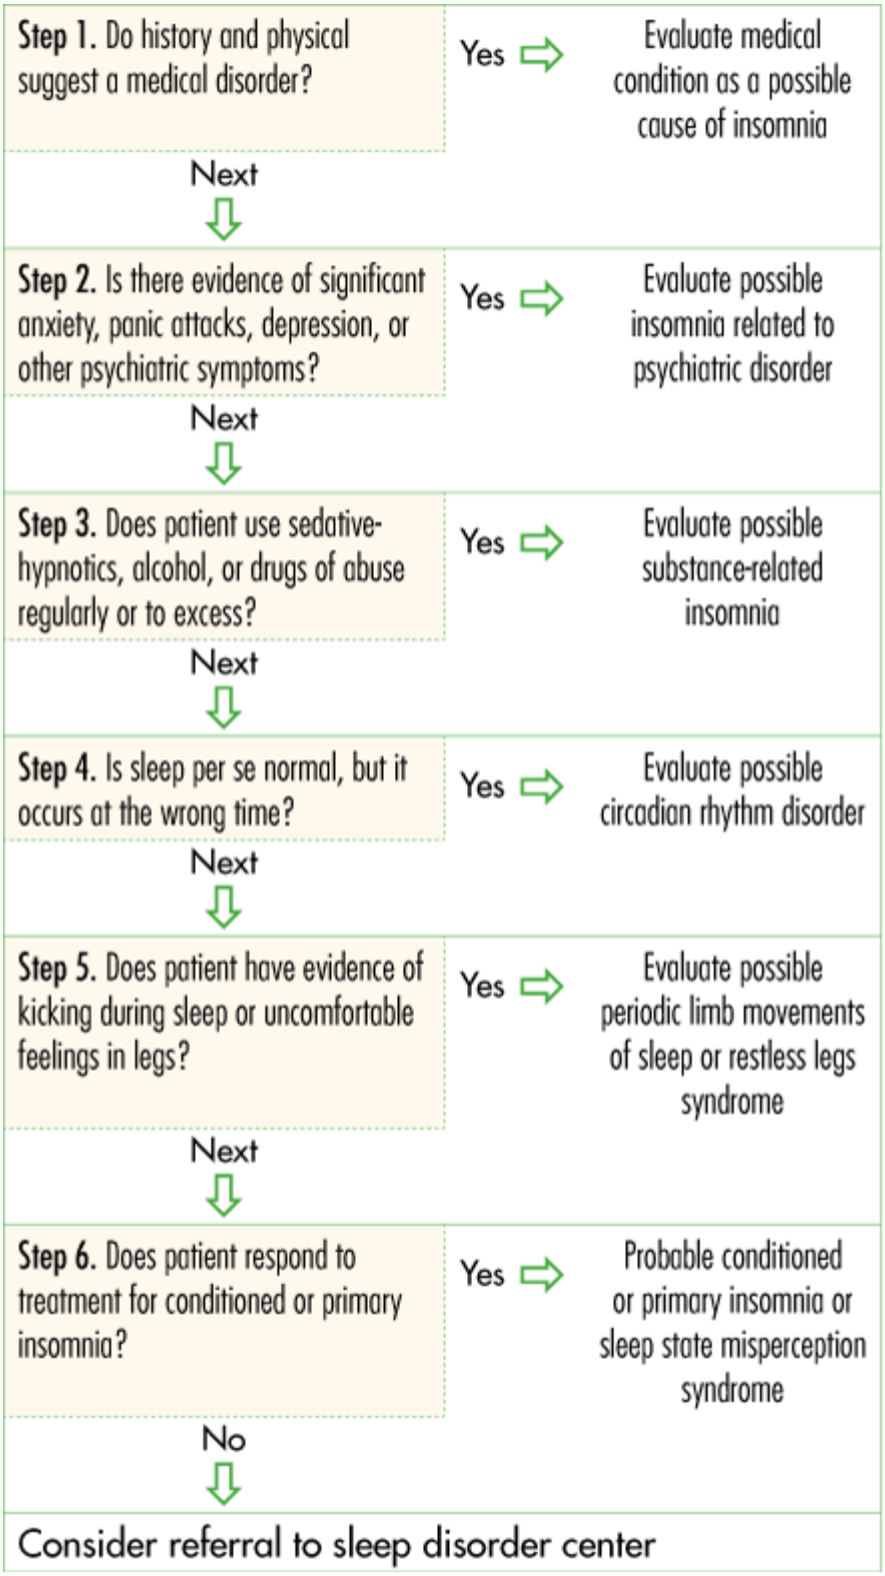
Chronic Insomnia

Chronic insomnia is of greater concern than short-term insomnia, as it is both common (the National Sleep Foundation estimates that 10%–15% of adults experience chronic insomnia) and results in substantial adverse effects on health, quality of life, and overall function, as reviewed by Krystal (2007). Chronic insomnia in adults is a risk factor for the development of anxiety and depression (Neckelmann et al. 2007; Richardson 2000). Chronic insomnia in adolescents is a risk factor for development of early adult depression and substance abuse (Roane and Taylor 2008). Chronic insomnia should be viewed not just as a sleep problem but also as a problem affecting the individual 24 hours a day.

DIFFERENTIAL DIAGNOSIS OF THE CHRONIC INSOMNIA COMPLAINT: A SIX-STEP DECISION PROCESS

The differential diagnosis and effective treatment of chronic insomnia can challenge the most skilled clinician. With chronic insomnias, unlike transient and short-term insomnias, the primary cause is rarely immediately apparent, and the likelihood of more than one cause is high. Accurate diagnosis is important because different causes of insomnia can present in a similar fashion, and the appropriate treatment for one may aggravate another. Failure to systematically pursue a complete differential diagnosis may yield misdiagnoses, treatment failures, and dissatisfied patients. Most patients with chronic insomnia present with a straightforward complaint of insomnia; however, it is important to realize that a substantial disturbance in nocturnal sleep can present as complaints of chronic fatigue, impaired daytime performance, and excessive daytime sleepiness (EDS), which raises the question of a possible excessive sleep disorder. A careful history should identify such patients so that a more appropriate inquiry into nocturnal sleep habits and patterns can be undertaken. Similarly, a large variety of medical and psychiatric disorders (and sometimes their treatments) are accompanied by insomnia complaints.

First in order in any patient is a *detailed sleep history,* which will include the type of insomnia problem (sleep onset, sleep maintenance, early awakening), when it began (childhood, recently, at time of major stress or life event), when it occurs (every night, weeknights only, at times of stress), what has been done when and by whom, previous response to treatment, how the insomnia affects daytime functioning, and similar issues. Family history is important since there are substantial genetic contributions both to basic sleep control mechanisms and to sleep pathologies (Hamet and Tremblay 2006). Development of atypical sleep-related habits counter to those of good sleep hygiene should be inquired about. A sleep diary kept for 1–2 weeks may be helpful in establishing the type, perceived



severity, and periodicity of the insomnia.

For this group of insomnias, the clinician should first establish that the patient has a true insomnia and is not just a typical short sleeper. Short sleepers, although not common, do exist and may get along fine on 4–5 hours of sleep a night. They do not complain of EDS or fatigue, and usually they have no sleep complaints. Their families, however, see the patient up until midnight and then out of bed again at 4:00 A.M. and assume that he or she has a sleep problem and convince him or her to seek professional help. Such individuals need no specific treatment, although an explanation is helpful for family members.

It is also important to decide whether the insomnia reflects a problem with non-REM or slow-wave sleep (more often) or REM sleep (less often). REM sleep–related insomnia complaints can result from frequent awakenings from frightening dreams or nightmares or from REM sleep behavior disorder (RBD). RBD is most often seen in older males and results from failure of proper skeletal muscle inhibition during REM such that patients can act out their dreams, often resulting in very disturbed sleep. Memory of dream content during the episode suggests RBD, which can be confirmed by polysomnography (Schenck and Mahowald 2005).

With this information on hand, the differential diagnosis is facilitated by a systematic approach such as that outlined in the schematic decision tree in Figure 60–1.

FIGURE 60–1. Differential diagnosis decision tree for chronic insomnia.

Step 1. Do history and physical suggest a medical disorder?
Yes
Evaluate medical condition as a possible cause of insomnia
Next
Step 2. Is there evidence of significant anxiety, panic attacks, depression, or other psychiatric symptoms?
Yes
Evaluate possible insomnia related to psychiatric disorder
Next
Step 3. Does patient use sedative-hypnotics, alcohol, or drugs of abuse regularly or to excess?
Yes
Evaluate possible substance-related insomnia
Next
Step 4. Is sleep per se normal, but it occurs at the wrong time?
Yes
Evaluate possible circadian rhythm disorder
Next
Step 5. Does patient have evidence of kicking during sleep or uncomfortable feelings in legs?
Yes
Evaluate possible periodic limb movements of sleep or restless legs syndrome
Next
Step 6. Does patient respond to treatment for conditioned or primary insomnia?
Yes
Probable conditioned or primary insomnia or sleep state misperception syndrome
No
Consider referral to sleep disorder center

Note. SMSS = sleep state misperception syndrome.

Step 1—Medical Conditions Affecting Sleep

Medical conditions, as well as the pharmacological treatments of medical conditions, can result in insomnia complaints. The endocrinopathies are notorious for being associated with sleep-related

complaints, as are conditions associated with chronic pain, breathing difficulties, cardiac arrhythmias, arthritis, renal failure, and central nervous system (CNS) disorders, especially the dementias. Evaluation may include a complete medical history and, if appropriate, a physical examination with relevant laboratory tests. Keep in mind the fact that the incidence of medical disorders accompanied by sleep complaints increases with age. Some of the more common medical disorders associated with impaired sleep are listed in Table 60–2.

TABLE 60–2. Medical conditions commonly associated with impaired sleep

Cardiovascular disorders
Angina
Congestive heart failure
Ischemic heart disease
Pulmonary disorders
Chronic obstructive pulmonary disease
Cystic fibrosis
Asthma
Sleep apnea
Dyspnea from any cause
Neurological disorders
Dementias
Parkinson's disease
Central nervous system degenerative disorders
Traumatic brain injury
Central nervous system neoplasms
Endocrinological disorders
Hyperthyroidism
Hypothyroidism
Cushing's syndrome
Addison's disease
Gastrointestinal disorders
Gastroesophageal reflux
Peptic ulcer disease
Genitourinary disorders
Nocturia
Renal failure
Immunological and rheumatic disorders
Rheumatoid arthritis

Osteoarthritis

Fibromyalgia

Pain and fever from any cause

Metabolic disorders such as diabetes

Sleep-related breathing disorders are frequently associated with insomnia complaints. Obstructive and mixed apneas are usually accompanied by other symptoms, such as snoring, excessive daytime sleepiness, and possibly cognitive problems. Central apnea is an occasional, albeit uncommon, cause of chronic insomnia, especially in older patients and at higher altitudes. The clinician should inquire whether the patient has had any subjective sense of trouble getting his or her breath or feeling like his or her breathing is interfered with, especially during the transition from wakefulness to sleep. Also ask the bed partner whether the patient has irregular breathing or pauses in his or her breathing during sleep. Snoring may be another clue (although it is more likely related to an obstructive component). Frequent apneas cause sleep fragmentation, which results in insomnia complaints and often complaints of increased daytime sleepiness (Bonnet and Arand 1997). Central sleep apnea is frequently associated with medical and neurological disorders (Thalhofer and Dorow 1997), but it may also occur in otherwise healthy individuals. It is more frequently encountered in older individuals (Ancoli-Israel et al. 1997). Both oxygen and continuous positive airway pressure (CPAP) can be used in the treatment of central apnea in patients with medical disorders (Franklin et al. 1997; Granton et al. 1996). The pharmacological treatment of central sleep apnea is less than optimal. Therapeutic options might include protriptyline (5–20 mg at bedtime), fluoxetine (10–20 mg/day), or theophylline (300–600 mg/day) (Ancoli-Israel et al. 1997), although their efficacy has yet to be clearly established in well-controlled studies.

Also, a number of prescription drugs may result in insomnia complaints (prescription drug use also tends to increase with age). Commonly used medications that can produce insomnia complaints in some patients are listed in Table 60–3.

TABLE 60–3. Commonly used drugs with insomnia as a side effect

β-Blockers

Corticosteriods

Adrenocorticotropic hormone

Monoamine oxidase inhibitors

Phenytoin

Calcium channel blockers

α-Methyldopa

Bronchodilators

Stimulating tricyclics

Stimulants

Some selective serotonin reuptake inhibitors

Thyroid hormones

Oral contraceptives

Antimetabolites

Some decongestants

Thiazides

No specific sleep abnormalities are usually associated with most medical disorders other than usually a decrease in total sleep, an increase in awakenings, and perhaps decreases in REM sleep. Fibromyalgia and chronic fatigue syndrome are very frequently associated with sleep complaints. On occasion, fibromyalgia is associated with an alpha–delta type of sleep abnormality, in which alpha frequency activity is accentuated in the slow-wave-sleep background, with a complaint of nonrestorative sleep. This pattern suggests a state of CNS hyperarousal. Sleep complaints are very common in chronic fatigue syndrome and can include insomnia, hypersomnia, nonrestorative sleep, and sleeping at the wrong time of the 24-hour period (circadian rhythm abnormalities). Conventional polysomnographic findings are generally nonspecific and include decreased sleep efficiency, decreased slow-wave sleep, increased sleep latency, and alpha–delta sleep EEG patterns (VanHoof et al. 2007). Chronic fatigue–related disturbances in regulation of underlying sleep control mechanisms are supported by several studies. One recent study found an increase in the cyclic alternating pattern in polysomnograms of chronic fatigue patients complaining of nonrestorative sleep (Guilleminault et al. 2006), and there is also evidence of decreased sleep drive (Process S) in chronic fatigue syndrome (Armitage et al. 2007).

Treatment of insomnia associated with medical conditions involves first isolating and appropriately treating the medical condition and then, if the insomnia complaint persists, evaluating the possibility of a separate additional sleep disorder. Conditioned insomnia can complicate insomnia complaints in this population, and it must be separately addressed (as outlined below). Similarly, it is quite possible for a patient with primary insomnia also to have a medical condition that further disrupts sleep. A study by Rybarczyk et al. (2005) indicated that cognitive-behavioral therapy (CBT) may be effective in older patients with insomnia comorbid with other medical conditions, such as osteoarthritis, coronary artery disease, or pulmonary disease, suggesting that CBT should be considered in these conditions.

Insomnia associated with acute medical conditions is appropriately treated with short-half-life hypnotic agents (e.g., zolpidem 5–10 mg, triazolam 0.125–0.25 mg, or eszopiclone 2–3 mg at bedtime) if no other contraindication to their use exists. Insomnia complaints associated with fibromyalgia and chronic fatigue syndrome are frequently resistant to treatment, although small doses of amitriptyline (10–50 mg at bedtime) or cyclobenzaprine (10 mg three times a day) have been reported to be helpful, and occasionally zolpidem (5–10 mg) will help with the associated insomnia complaints.

Scharf et al. (2003) reported that treatment with sodium oxybate (Zyrem) improved both sleep abnormalities and symptoms of pain and fatigue in patients with fibromyalgia. Edinger et al. (2005) found that CBT was effective in treating sleep complaints in patients with fibromyalgia. Modafinil has been reported to decrease daytime fatigue and sleepiness in fibromyalgia patients, but its impact on sleep has not yet been reported (Schaller and Behar 2001). If a medical disorder is suspected of causing or contributing to the sleep complaint, a change of or alterations in treatment that might improve sleep should be considered. It is important, however, to remember that the differential diagnosis of a chronic insomnia complaint does not stop here—the remainder of the differential diagnosis should be completed.

***Dementing illnesses* such as Alzheimer's disease are often associated with severe insomnia complaints that are quite disruptive to patients and families and often are the factors precipitating institutional care. Disease-associated neuropathological changes in the sleep and circadian rhythm control centers in the hypothalamus and SCN may contribute to these symptoms. Patients with Alzheimer's disease demonstrate phase-delayed body temperature and activity rhythms, with delayed sleep onset, increased nocturnal activity, and fragmented sleep, likely related to disease-associated SCN lesions. Some evidence suggests that a melatonin deficiency may be present in some patients with Alzheimer's disease (Liu et al. 1999). Sleep is also disturbed in dementia with Lewy bodies (DLB), which has been**

found in up to 20% of dementia cases referred to autopsy (McKeith 2000); this disturbance is often in the realm of increased motor activity suggestive of an REM behavior disorder (Boeve et al. 1998; Ferman et al. 1999). Clearly, then, sleep and activity abnormalities associated with dementia may result from very different pathophysiologies and thus might respond to different treatments. Until such specific treatments can be based on specific pathophysiology, we should adhere to optimal environmental circadian principles (quiet, dark nocturnal environment; bright, socially stimulating daytime environment). Possible supplementation with evening melatonin and additional morning bright light may prove useful, in addition to the appropriate use of sedative-hypnotic agents, with the proviso that CNS lesions may significantly impact the response to hypnotic agents. There is evidence that behavioral treatment methods may benefit some Alzheimer's patients (McCurry et al. 2004).

Step 2—Psychiatric Disorders

The presence of significant anxiety, dysphoric or cyclic mood, or frank depression with sleep complaints should alert the clinician to a possible *psychiatric-related insomnia.* Nocturnal panic attacks can result in insomnia complaints, even in individuals who do not have typical panic episodes during the day. Accordingly, the clinician should pay special attention to evidence of nocturnal arousals accompanied by autonomic symptoms such as tachycardia, rapid breathing, and the sense of anxiety or fearfulness. Insomnias related to psychiatric causes usually covary with the degree of psychiatric symptoms. The fear of not being able to get to sleep seen in patients with conditioned insomnia ("I can't turn off my thoughts") sometimes can be difficult to distinguish from anxiety, but treatments may differ (e.g., CBT for conditioned insomnia, anxiolytics for anxiety).

Psychiatric disorders, especially disorders associated with anxiety or depression, frequently include insomnia as an associated symptom. Chronic anxiety is not infrequently associated with sleep-onset insomnia or sleep-maintenance insomnia, whereas depression is not infrequently associated with early-morning awakening. These associations are not specific enough to be diagnostic, however, and a systematic psychiatric evaluation is necessary. Many depressive disorders appear to be accompanied by shortened REM latency, increased REM density during the first REM period of the night, and deficient slow-wave sleep. To date, however, such findings are not sufficiently specific to merit the cost of a polysomnogram.

Antidepressant agents, although effective for the patient's depression, may have significantly different effects on sleep—a possibility that is useful to bear in mind. Table 60–4 shows sleep-related effects of the major antidepressant groups.

TABLE 60–4. Overview of the effects of antidepressants on sleep

Drug	Continuity	SWS	REM sleep	Sedation
TCAs				
Amitriptyline (Elavil)	↑↑↑	↑	↓↓↓	+ + + +
Doxepin (Sinequan)	↑↑↑	↑↑	↓↓	+ + + +
Imipramine (Tofranil)	↔↑	↑	↓↓	+ +
Nortriptyline (Pamelor)	↑	↑	↓↓	+ +
Desipramine (Norpramin)	↔	↑	↓↓	+
Clomipramine (Anafranil)	↑↔	↑	↓↓↓↓	±
MAOIs				
Phenelzine (Nardil)	↓	↔	↓↓↓↓	↔

Drug	Continuity	SWS	REM sleep	Sedation
Tranylcypromine (Parnate)	↓↓	↔	↓↓↓↓	↔
SSRIs				
Fluoxetine (Prozac)	↓	↔↓	↔↓	±
Paroxetine* (Paxil)	↓	↔↓	↓↓	±
Sertraline (Zoloft)	↔	↔	↓↓	↔
Citalopram (Celexa)	↓	↔	↓	↔
Fluvoxamine (Luvox)	↓	↔	↓	+
Others				
Bupropion (Wellbutrin)	↓↔	↔	↑	↔
Venlafaxine (Effexor)	↓	↔	↓↓	++
Trazodone (Desyrel)	↑↑↑	↔↑	↓	++++
Mirtazapine (Remeron)	↑↑	↔↑	↔↓	++++
Duloxetine (Cymbalta)	↔	↔	↓	↔

Note. ↑ = increased; ↓ = decreased; ↔ = no change; + = slight effect; ++ = small effect; +++ = moderate effect; ++++ = great effect; ± = no significant effect. EEG = electroencephalogram; MAOIs = monoamine oxidase inhibitors; REM = rapid eye movement; SSRIs = selective serotonin reuptake inhibitors; SWS = slow-wave sleep; TCAs = tricyclic antidepressants.
*When taken at bedtime, paroxetine potentially decreases sleep continuity less than other SSRIs.

Source. Adapted from Winoker A, Reynolds C: "Overview of Effects of Antidepressant Therapies on Sleep." *Primary Psychiatry* 1:22–27, 1994. Used with permission.

The choice of an antidepressant agent for a specific patient, all other things being equal, might well take into account the type of accompanying sleep complaint and the therapeutic effect on sleep desired. Typically, resolution of the depression will be accompanied by reduction in the sleep complaints. If, for a patient already complaining of insomnia, an antidepressant with a known high incidence of insomnia side effects is chosen, it may be useful to augment it with a hypnotic agent early in the course of treatment.

Treatment of insomnia associated with anxiety can incorporate a benzodiazepine with sedative-hypnotic properties with a sufficient bedtime dose to augment sleep. Many antianxiety agents, such as sedative tricyclics, have sedative-hypnotic properties as well, which facilitate the management of the insomnia component. Panic attacks can occasionally arise exclusively from sleep (Rosenfeld and Furman 1994); treatment in such cases should probably follow conventional panic attack treatment strategies. Mirtazapine, an antidepressant with antianxiety properties (Anttila and Leinonen 2001), may be helpful in the management of some cases of anxiety with insomnia.

Bipolar disorder may be accompanied by prominent sleep disruption. Manic and hypomanic episodes may be accompanied by marked decreases in sleep, although not necessarily insomnia complaints. Sedative antidepressants have been shown to increase the risk of a shift to mania in treating insomnia complaints in bipolar depressed patients (Saiz-Ruiz et al. 1994), and the use of other hypnotic agents would therefore be more advisable in these patients. Milder cyclic mood disorders also may have associated insomnia complaints, which can be mistaken for a primary insomnia or a conditioned arousal insofar as the patients find it difficult to turn off their thinking at sleep onset or after awakening during the night. If these patients are questioned carefully, evidence of a cyclic mood

component will suggest that treatment with a mood stabilizer might be appropriate for the chronic insomnia complaint in these patients.

Posttraumatic stress disorder (PTSD) is a psychiatric disorder in which sleep disturbances are a hallmark. Patients with PTSD may exhibit increased sleep latency, decreased sleep efficiency, recurrent traumatic dreams, and evidence of increased REM density (Mellman et al. 1997), as well as evidence of impaired skeletal muscle inhibition during REM sleep (Ross et al. 1994). Chronic nightmares in PTSD have been successfully treated with CBT (Davis and Wright 2007). Recent reviews suggest that a variety of medications may be useful for insomnia problems associated with PTSD, including the atypical antipsychotic olanzapine and the α_1-adrenoreceptor antagonist prazosin, and possibly serotonin 2 ($5\text{-}HT_2$) receptor antagonists (van Liempt et al. 2006), and residual insomnia in PTSD patients has been treated with CBT (Deviva et al. 2005). Overall, however, satisfactory treatment of sleep problems in PTSD remains elusive.

Step 3—Substance Misuse

A careful drug history will help to identify those patients who have used sedatives or hypnotics, including alcohol, nightly for many months to years in order to fall asleep and who have developed a chronic *insomnia secondary to substance misuse.* Similarly, a history of stimulant use or other inappropriate drug use may result in a sleep disorder. A history of chronic or excessive drug or alcohol use recounted by the patient or, equally important, by a family member or friend suggests that further workup in this area is required. Psychotropic dependence—the perceived need to "take a pill" to diminish anxiety about potentially not being able to sleep—is not always easy to distinguish from physical dependence—the actual need for the physiological effects of medication in order to maintain sleep.

Alcohol remains a significant problem, as do stimulants and other drugs of abuse. Alcohol-dependent sleep disorder occurs in those who habitually "self-medicate" with alcohol to induce sleep. Alcohol does tend to decrease sleep latency and wakefulness during the first 3–4 hours of sleep. It also suppresses REM sleep and leads to REM rebound (with the possibility of vivid dreams or nightmares), with fragmented sleep during the latter part of the night. Treatment includes withdrawal of alcohol, with long-term abstinence as the goal. When necessary, sedation can be provided by judicious use of antihistamines (e.g., diphenhydramine [25–50 mg] or cyproheptadine [4–24 mg]).

Chronic use of stimulants leads to prolonged sleeplessness, and their withdrawal is followed by a period of hypersomnolence. A chronic insomnia complaint is often seen in long-term stimulant abusers even when they are not actively abusing the agents. Treatment is similar to that of alcohol-induced sleep disorder. Antikindling agents such as carbamazepine (100–600 mg/day) or divalproex (250–1,500 mg/day) may help when CNS hyperarousal/kindling is evident, as is sometimes seen in postcocaine panic disorder in polysubstance abusers.

Habituation to benzodiazepine agents does not usually result in insomnia unless they are too rapidly withdrawn, in which case the withdrawal syndrome may include insomnia. Doses should be tapered by one therapeutic dose per week.

In all cases of substance abuse sleep disorders, the insomnia complaint should emphasize behavioral treatment strategies to the fullest extent possible because psychoactive agents have already proved to be a problem.

Step 4—Circadian Rhythm Disorders

Circadian rhythm disorders often present as sleep complaints. The most common is the delayed sleep phase syndrome (DSPS), which presents as sleep-onset insomnia. Typically, individuals with DSPS cannot get to sleep until 3:00–4:00 A.M. If they can then sleep until 10:00 A.M. or noon the next day, they can do fine, indicating that they may have no trouble initiating or maintaining sleep, but if they

are required to arise early to get to school or work, they complain of insomnia, and they are, of course, sleep deprived. Individuals with DSPS typically sleep in on weekends to recoup lost sleep. They often have already tried hypnotics, which are generally ineffective other than in inducing drowsiness, and their complaints are usually long-standing. DSPS typically appears in adolescence or early adulthood, and it is frequently familial. Often first-degree relatives have a history of similar sleep patterns.

In DSPS patients, evidence indicates that temperature rhythms and sleep rhythms are delayed and that possibly sleep persists for a longer time following the body temperature low point, suggesting that these patients may continue to sleep through the period when bright light would be most effective in phase-advancing their circadian system (Ozaki et al. 1988). Melatonin rhythms also may be phase-delayed in DSPS (Shibui et al. 1999).

Other forms of circadian rhythm disorders presenting as sleep complaints include advanced sleep phase syndrome (ASPS) and non-24-hour sleep–wake syndrome, also known as hypernychthemeral syndrome (Richardson and Malin 1996). ASPS is accompanied by retiring very early in the evening and correspondingly arising very early in the morning, a schedule that sometimes mimics that of terminal insomnia. Patients with the hypernychthemeral syndrome experience a failure of the circadian clock to entrain normally to the 24-hour day, and they sometimes experience a free-running 25-hour rhythm. This disorder is especially prevalent in blind persons, for whom light is unable to synchronize the circadian system. Some blind persons, however, are sensitive to light as an entrainer of the circadian system so long as the retina and retinohypothalamic tract are functioning normally.

Treatment of circadian rhythm–based sleep disorders now most often includes both bright light and melatonin. Early-morning bright-light exposure administered after the body temperature low point, with restriction of light exposure in the evening, has been found to be effective for phase-advancing the circadian system in DSPS (Regestein and Pavlova 1995; Rosenthal et al. 1990). Evening bright-light treatment has been found to be effective in phase-delaying the circadian system and in effectively treating ASPS (Chesson et al. 1999). Melatonin has also been used successfully in the treatment of DSPS (Dahlitz et al. 1991; Lamberg 1996; Szeinberg et al. 2006), and a case report indicated its successful use in entraining the circadian system in a blind, mentally retarded child who was unresponsive to bright light (Lapierre and Dumont 1995). Melatonin is also effective in synchronizing the free-running circadian rhythm in blind persons (Lewy et al. 2006).

Step 5—Movement Disorders: Restless Legs Syndrome and Periodic Leg Movements in Sleep

Restless legs syndrome (RLS) is not a true sleep disorder but rather a movement disorder that interferers with sleep. RLS is characterized by uncomfortable sensations in the calves at sleep onset that require that the patient get up and "walk them out." RLS symptoms are often maximal between the hours of 10 P.M. and 2 A.M., thus interfering with sleep. Severe untreated cases can be associated with significant sleep impairment and even skeletal injury (Kuzniar and Silber 2007). RLS is increased in pregnancy, iron deficiency, renal disease, and diabetic neuropathy. There are genetic contributions to RLS, and several candidate gene loci have been identified (Winkelmann et al. 2007). While its pathophysiology remains unclear, some evidence suggests that RLS is associated with increased intracortical excitability that can be reversed by the dopamine D_2 receptor agonist cabergoline (Nardone et al. 2006).

Treatment for RLS should take into account severity, and division of patients into three groups has been suggested: 1) those with intermittent RLS symptoms, 2) those with daily RLS symptoms, and 3) those with symptoms refractory to common treatments. Both behavioral and pharmacological strategies should be employed, and treatment algorithms are available (Hening 2007). Dopamine agonists have been used for treatment of RLS. Carbidopa or levodopa was used initially but frequently led to augmentation, or worsening of symptoms, with time. Ropinirole 0.5–6 mg/day in divided doses,

and pramipexole 0.125–0.75 mg have been shown to be effective in treating RLS. Gabapentin 300–1,200 mg has also been found helpful (Happe et al. 2003)

Because iron deficiency can be a cause of RLS, iron supplementation can often be helpful, especially if serum ferritin levels are below 45 µg/L (O'Keeffe 2005). Some evidence suggests a deficiency of iron transport into the CNS in RLS (Connor et al. 2003), and the use of intravenous iron has been reported to be helpful in severe cases but is not yet an approved treatment modality.

Periodic leg movements in sleep (PLMS; formerly termed nocturnal myoclonus) consist of periodic leg jerks occurring during sleep. Physiologically they appear to consist of extensions of the great toe and dorsiflexion of the ankle, knee, and hip, and they may represent the release of Babinski-type reflexes due to enhanced spinal cord excitability during light sleep. Associated muscle contractions are usually short (0.5–1.0 second) in duration and periodic (every 20–40 seconds), with recurrent episodes. They may be associated with EEG arousals or with cyclic-alternating-pattern discharges in the EEG. There is disagreement as to whether PLMS constitutes a form of sleep pathology that should be evaluated for treatment (Hogl 2007) or a normal variant with little clinical significance and not requiring treatment (except perhaps for the bed partner experiencing the kicking activity) (Mahowald 2007). In any case, dopaminergic agents as used for RLS are the treatments of choice, but the issue remains unresolved, and individual cases should be evaluated in the context of the latest medical literature.

Step 6—Conditioned Insomnia, Primary Insomnia, and Sleep State Misperception Syndrome Group

Finally, after the foregoing causes have been ruled out, a persistent chronic insomnia complaint likely falls into what we term the *conditioned insomnia/primary insomnia/sleep state misperception syndrome category.* This group has often been characterized as "psychophysiological insomnia" (American Academy of Sleep Medicine 2005), a term recently resurrected in the latest International Classification of Sleep Disorders (ICSD) that, while likely correct in that insomnia has both psychological and physiological components, is not of great help in separating independent causes that may respond to separate treatments. *Primary insomnia* is a DSM-IV-TR (American Psychiatric Association 2000) diagnostic with emerging information on the pathophysiology underlying its apparent chronic physiological hyperarousal. *Conditioned insomnia* is, as the name suggests, a "learned insomnia" in which a susceptible individual, after having trouble sleeping for a few nights, becomes fearful, with accompanying hyperarousal, about the very thought of going to bed or even going into the bedroom. The *sleep state misperception syndrome* is an interesting if still poorly understood condition that can be initially confusing, for these individuals appear unable to recognize that they have been asleep. These three types (as used here) of chronic insomnia tend to have a commonality of treatment approaches, which will likely continue to be the case until we have more data on their specific independent pathophysiologies. From a statistical and epidemiological standpoint, this category, in combination with the psychiatric causes of poor sleep, represents overall the largest group of the chronic insomnias. We believe it useful to attempt to separate the members of this category, even though they respond to the same treatment approaches. We will consider these three syndromes independently, first defining each as best we can and then discussing the common differential diagnosis and treatments options.

Conditioned Insomnia

The presenting symptoms for conditioned insomnia are as follows:

- Insomnia complaint, in a susceptible individual, beginning at a time of stress but persisting after the resolution of the stress
- Fear of going to bed because of the difficulty getting to sleep
- Racing thoughts when finally lying down and trying to sleep (must be differentiated from anxiety and mood dysregulation)

- May not be present in alternative sleep environment (couch, sleep lab, another home)

Conditioned insomnia is a learned arousal state. Typically beginning at a time of stress in susceptible individuals (those with a history of fragile or easily interrupted sleep), a few nights of trouble getting to sleep or staying asleep lead to development of a fear of going to bed because of concern that sleep again will be difficult to initiate or maintain. This fear is associated with increased cognitive and physiological arousal, and soon a vicious cycle is established in which merely going into the bedroom to prepare for sleep results in a conditioned arousal response sufficient to interfere with sleep. More specifically, these individuals develop a "conditioned arousal" to the normal sleep environment.

The conditioned arousal can continue long after resolution of the initial stress, and the resulting insomnia complaint can be quite chronic. Such individuals may be able to sleep on the living room couch, because they are conditioned to arouse only in their own bedroom. They may be able to nap during the day, and often sleep well on vacation or in a new environment. They may also sleep normally in the sleep lab, which is a new environment in which they may not experience conditioned arousal. Thus, a normal polysomnogram does not mean that the patient does not experience insomnia at home. Frequently, such individuals complain of not being able to turn off their thoughts at bedtime and recognize that they become fearful and aroused at the thought of going to bed. The differential diagnosis includes anxiety disorders and racing thoughts associated with a mildly hypomanic state, such as may accompany bipolar II disorder. Not surprisingly, conditioned arousal can co-occur with and complicate other causes (e.g., medical, psychiatric) of insomnia, having developed in response to the sleep difficulties associated with those disorders.

Primary Insomnia

The presenting symptoms for primary insomnia are as follows:

- Complaint of chronic insomnia 1 month or more in duration (sometimes years), that may wax and wane in intensity and appears independent of stressful or life events.
- Little evidence of fear about going to bed or complaints of racing thoughts.
- Other causes of chronic insomnia have been ruled out, or if present appropriately treated.

DSM-IV-TR criteria for primary insomnia are listed in Table 60–5.

TABLE 60–5. DSM-IV-TR diagnostic criteria for primary insomnia

A. The predominant complaint is difficulty initiating or maintaining sleep, or nonrestorative sleep, for at least 1 month.

B. The sleep disturbance (or associated daytime fatigue) causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The sleep disturbance does not occur exclusively during the course of narcolepsy, breathing-related sleep disorder, circadian rhythm sleep disorder, or a parasomnia.

D. The disturbance does not occur exclusively during the course of another mental disorder (e.g., major depressive disorder, generalized anxiety disorder, a delirium).

E. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.

Recent evidence suggests a state of hyperarousal may accompany and possibly be a cause of primary insomnia. These patients evidence increases in brain metabolism using positron emission tomography (PET) neuroimaging both while awake and during sleep compared with normally sleeping control subjects (Nofzinger et al. 2004), and evidence of increased metabolism during NREM sleep using single photon emission computed tomography (SPECT) imaging (Smith et al. 2002). They also evidence increased fast-EEG activity during sleep (Merica et al. 1998; Perlis et al 2001a, 2001b). There may be genetic contributions, although specifics remain to be determined (Heath et al. 1990).

The important point is that this may be a bona fide medical disorder requiring long-term management, including possibly long-term medication for sleep.

Sleep State Misperception Syndrome

Sleep state misperception syndrome (SSMS), a somewhat confusing term and a still poorly understood condition, characterizes individuals who may go to sleep, spend time asleep, and awaken, and yet not be aware of having slept. If sleep lab studies are performed to investigate the chronic insomnia complaint, findings may appear normal. However, despite evidence of normal or near-normal sleep, SSMS patients may still have symptoms seen in other patients with chronic insomnia, such as disturbed daytime vigilance (Sugerman et al. 1985). Interestingly, a "reverse sleep state misperception syndrome" has also been reported, in which a patient reported having slept normally while objectively awake (Attarian et al. 2004).

Physiological studies are sparse. One study reported evidence of increased basal metabolic rate in patients with SSMS compared with control subjects, but not as high as in psychophysiological insomnia (Bonnet and Arand 1997), and there is evidence of possible sleep EEG differences (increased faster rhythms) in SSMS (Edinger and Krystal 2003).

The extent to which sleep misperception may constitute a clinically meaningful subtype of chronic insomnia remains to be determined. Because the syndrome has yet to be objectively defined and requires objective evidence of lack of awareness of being in a state of EEG-defined sleep, the issue of etiology remains moot, although the usual suspects (genetics, impaired arousal regulation (cause), conditioning or learning, stress responses) come to mind.

Differential Diagnosis for the Conditioned Arousal, Primary Insomnia, and Sleep State Misperception Syndrome Group

Since other causes having already been eliminated, the major differential in the case of conditioned insomnia, sleep state misperception, and primary insomnia rests upon history, symptoms, and perhaps a polysomnogram (may be helpful in SSMS). An important aspect of conditioned insomnia is that it frequently complicates insomnias resulting from other causes, and requires independent assessment and treatment.

In conditioned insomnia, the history will often disclose a stressful event as initiating the insomnia, which continues after the event resolves. In conditioned insomnia, sleep complaints tend to be fixed over time, but they may covary with the degree of daytime stress. These patients often tend to be tense or "wired" individuals; thus, some individuals may be more prone than others to the development of psychophysiological insomnia. Sleep-onset insomnia does not always characterize this disorder. Some patients may be able to fall asleep rather easily, but then they may have several hours of wakefulness later in the night, again unable to turn off their thoughts. Primary insomnia tends to be more chronic without clear cut stressful initiating events. The separation of primary insomnia from chronic mild anxiety is sometimes difficult. SSMS patients may complain of getting absolutely no sleep at all—which of course is unlikely. The DSM-IV-TR criteria for primary insomnia need to be met. SSMS may not be suggested until a laboratory study (actigraphy or polysomnography) suggests a dissociation between subjective complaints and objective findings.

SLEEP LABORATORY STUDIES

Are sleep laboratory studies useful in any of the insomnias? In most cases—no. An all-night sleep study or polysomnogram may be indicated in chronic insomnia patients who are suspected of having either PLMS possibly causing insomnia or a SRBD, where identification and quantification is useful. Some conditioned insomnia patients may have less trouble sleeping in the laboratory environment than at home, which results in more normal-appearing polysomnographic findings. Thus, the presence of a relatively normal polysomnogram result in the laboratory does not exclude the possibility of real

sleep difficulties in the patient's regular sleep environment. A polysomnogram can be helpful in the case of SSMS, where the findings may be within normal limits even though the patient believes he or she has obtained little or no sleep. It is questionable, however, whether the cost–benefit ratio merits a polysomnogram in the latter cases, unless there are other reasons for the study (e.g., treatment nonresponsiveness).

Conventional polysomnography is designed primarily to quantify respiratory and related physiology as well as muscle activity, but it does not typically sample brain activity with sufficient temporal and spatial resolution to provide useful information about other insomnia conditions. A polysomnogram in insomnia typically shows evidence of increased sleep latency, more frequent awakenings, and lower-than-normal total sleep and sleep efficiency, but the patient has already told you that. Functional neuroimaging studies (high-density EEG or magnetoencephalography, PET, SPECT) are research tools of potential value in better understanding disturbances in brain function underlying insomnia complaints, but they are not yet of routine diagnostic utility for most insomnia patients.

Actigraphy, providing an objective measure of minute-to-minute activity over several days or weeks, may be helpful in suggesting a circadian rhythm disorder and sometimes SSMS, but while activity measures often correlate well with polysomnogram-determined sleep measures, actigraphy alone has not yet been shown to be accurate for diagnosis (Littner et al. 2003).

TREATMENT OF CHRONIC INSOMNIA

It is very important to realize that more than one cause of chronic insomnia may be present—in fact, it might be stated that *comorbidity is the rule, not the exception.* A patient may, for example, have a medical cause and a psychiatric cause in addition to PLMS or another movement disorder–related insomnia, and may then go on to develop a "conditioned" component. Patients who are depressed with comorbid insomnia may also have a primary insomnia disorder. Thus a complete differential diagnosis should be done for each patient, which should not stop when the first likely cause is identified. Similarly, treatments should be designed to cover all appropriate causes. The question of whether all appropriate treatments should be initiated together rather than waiting to see if the first treatment modality works alone before adding another is an important issue with no clear answer. Starting several at once risks overtreatment, whereas starting only one modality to see if it works before starting the others can mean delay in obtaining relief, furthering the belief that the insomnia is intractable and possibly even leading to the development or aggravation of a conditioned component. In the absence of firm rules, good clinical judgment and a good understanding of the patient are paramount.

Combined Treatment Approach for Chronic Insomnia

Recent years have seen major advances in both pharmacological and nonpharmacological (behavioral) treatments for insomnia (Erman 2005). These treatments will often be supplementary to the treatments designed specifically for medical, psychiatric, and other comorbidities, which may also be concurrent. As a general rule, a combined approach—utilizing both behavioral and pharmacological components—is preferable, recognizing that behavioral components may not always be available.

The mainstay of nonpharmacological behavioral treatments is CBT, which has been well documented as an effective strategy. Additional behavioral treatments include improved sleep hygiene, biofeedback, sleep restriction, progressive relaxation, and various meditation techniques. From the pharmacological standpoint, recent years have seen the development of a series of new nonbenzodiazepine hypnotic agents that are both more effective and less troublesome than the older benzodiazepine agents.

Nonpharmacological Treatments for Chronic Insomnia

Cognitive-Behavioral Therapy

CBT for chronic insomnia has proved effective in a number of recent studies (Morin 2004; Smith and Perlis 2006). CBT has three components—education, behavioral modification, and cognitive therapy (Morin 2004). The literature on CBT as an effective treatment for insomnia is extensive and compelling and was nicely reviewed by Morin (2004). Smith and Perlis (2006) outline its use as a first-line treatment for chronic insomnia, including insomnia comorbid with medical and psychiatric disorders. One recent study using CBT in the treatment of insomnia associated with breast cancer suggested improvement in both sleep and immunological function resulting from CBT (Savard et al. 2003). Two issues of concern are which patients are optimally suited (or not well suited) for CBT (Smith and Perlis 2006) and whether therapists trained in CBT are available. Recent reports indicate that CBT need not be a long-term and complex treatment program; indeed, a very brief two-session form of CBT has recently been described that can be effective in primary care settings (Edinger and Sampson 2003). Perlis et al. (2005) has published a manualized step-by-step cognitive-behavioral treatment program for insomnia that clinicians should be able to implement effectively.

Sleep Hygiene
